***Abstract*—This study aims to address the issue of predicting the ice load on overhead power lines using neural network modeling. This issue was implemented on the basis of a forecasting model with a 12-8-1 architecture using the method of sliding time windows in the STATISTICA environment. The average relative error of the air temperature forecast was 12.9 %, which confirms the reliability of the forecast model and the feasibility of using neural network modeling to solve forecasting problems in the energy sector. The presented scientific research can be successfully used by operators of the power distribution system to adjust the operation of power grids in accordance with the meteorological situation along the overhead line route.**

Keywords—electrical grid, neural network modeling, ice load, overhead line, predictive model, artificial neural network theory

I. Introduction

Meteorological conditions have a significant impact on the operation of overhead power lines, infrastructure integrity, and characteristics of electric power grids. Environmental parameters, such as temperature and humidity, wind speed, significantly affect the prediction of ice load formation on overhead power lines, the reliability of electricity transmission and consumption, and electricity losses in grid elements [1-3].

One of the main functional properties that is basic for the further development of electricity networks in order to increase the efficiency of controlling their operating modes is the control of current meteorological parameters and overhead line parameters with the function of their forecasting, which is based on various methods and models [4-6]. Integration of these approaches into the control information system will increase the efficiency of electricity networks operation. And monitoring of environmental parameters will allow us to move to more efficient electricity networks management. The observation data generated in the relevant database will be used to analyze, evaluate, and predict the meteorological situation along the overhead power line route in order to adjust the electricity networks operation mode control. To do this, it is necessary to solve the forecasting problem and the most effective way to solve it is neural network modeling [7, 8].

In addition, forecasting the ice load can help electricity distribution system operators prepare for possible emergencies in time and take appropriate measures. Therefore, the solution of forecasting problems of ice formation on overhead power lines is one of the priority areas of research in the energy sector.

The aim of the paper is to study the issue of predicting the ice load on overhead power lines using neural network modeling, which will allow adjusting the operation of power grids in accordance with the meteorological situation along the overhead line route.

II. Formation of a Model For Predicting Ice on Overhead Line Wires Using Neural Network Modeling

The basis for solving the issue of predicting the ice load on overhead lines is the data of control and measuring devices of ice load and meteorological parameters that are part of the information monitoring systems of overhead line parameters [1, 4, 6].

The main controlled parameter measured by the control and measuring devices is the wire weight (M). For the convenience of modeling, this parameter is expressed as a percentage of the weight of a clean wire, i.e. without ice loads. When ice forms, the weight begins to increase and can reach a critical value (M_c), determined by the design parameters of the line. The task of forecasting is to warn the operator of the power distribution system in advance about the probable excess of the critical value of the overhead line wire weight, taking into account the time required to make a decision and prepare for ice melting, the warning interval (h) in the studies is taken to be 2 hours.

In addition to the weight of the wire, the control and measuring device measures the temperature (T) and relative humidity (H) of the air, which directly affect the process of ice formation. Other meteorological parameters such as wind strength and direction, type and intensity of precipitation are not measured, as this causes certain technical difficulties and significantly increases the cost of the overhead line parameters measurement. Information is collected from the control and measuring devices in real time, then the data is averaged over the past hour, and these values are transmitted via the communication channel to the control center. The exception is the wire weight parameter, for which the maximum value recorded during the hour (M_{max}), is also transmitted, which can be used to indirectly judge the presence of a wind load on the overhead line wire.

To form a predictive model based on available archival observation data, it is advisable to apply the theory of artificial neural networks and neural network modeling [7-11].

Using neural network modeling algorithms, the predictive mathematical model will have the form [12]:

$$\widehat{M}(k+h) = F(M(k),\ \dots,\ M(k-d),\ M(k)(k-d)_{max},\ T(k),\ \dots,\ T(k-d),\ H(k),\ \dots,\ H(k-d)), \quad (1)$$

Here k is the hour number; d is the order of the model corresponding to the depth of the used background; $F(?)$ is the requested, in the general case, nonlinear transformation.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

To implement model (1), it is advisable to use the architecture of a network formed on hybrid neural-like elements [9-12] (Fig. 1).

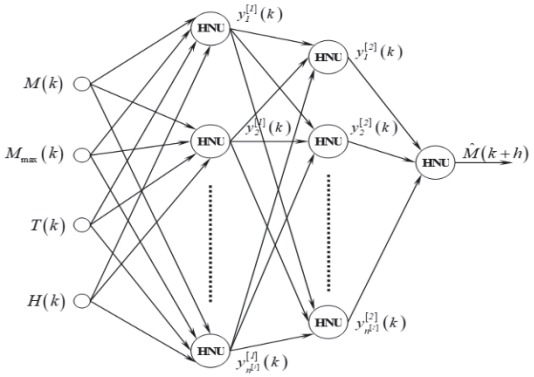

Fig. 1. Network architecture based on hybrid neural units (HNU)

This network (Fig. 1) has properties with some additional features that are achieved by deepening the specialization of artificial neural network architectures by moving from the level of selecting neuron types to the level of selecting the types of individual synapses [9, 11, 12].

The input signals of the network are the current values of the predicted variable *M(k)* and the measured values $M(k)_{max}$. There is no need to input the measurement history, since it is formed automatically inside the hybrid neural units (HNUs), the structure of which is shown in Fig. 2 [12].

During the research, a nonlinear synapse based on a fuzzy system (Fig. 3) is used in the neuro-like element (Fig. 2) [10, 12].

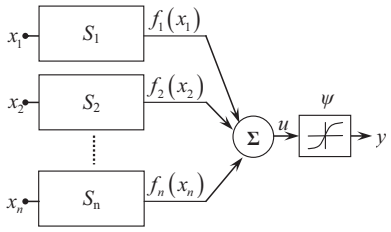

Fig. 2. Hybrid neuronal element

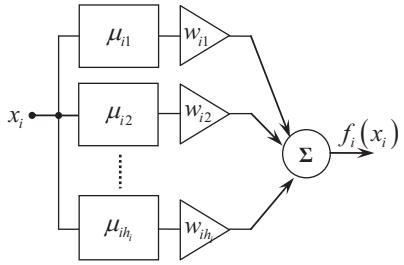

Fig. 3. A nonlinear synapse based on a fuzzy system

In nonlinear synapses based on a fuzzy system (Fig. 3), triangular membership functions are usually used, the values of which are determined by the distance between the input x_i and the centers c_{ij} [9, 12]:

$$\mu_{ij}(x_i) = \begin{cases} \frac{x_i - c_{i,j-1}}{c_{ij} - c_{i,j-1}}, x_i \in [c_{i,j-1}, c_{ij}]; \\ \frac{c_{i,j+1} - x_i}{c_{i,j+1} - c_{ij}}, x_i \in [c_{ij}, c_{i,j+1}]; \\ 0 \text{ otherwise}, \end{cases} \quad (2)$$

Under such conditions, the Ruspini partition is automatically provided $\sum_{j=1}^{h_i} \mu_{ij}(x_i) = 1, \forall i$ [8, 10, 11].

The use of hybrid neural-like elements allows building a neural network according to a standard multi-layer architecture, the specialization of which is achieved by: choosing the type of synapse for each network connection, including the possibility of a connection break - the absence of a synapse; choosing the number and order of delay elements in synapses - filters with finite and infinite impulse responses; choosing the number and parameters of membership functions in nonlinear synapses [8-12].

III. Development of a Training Algorithm for a Model for Predicting Ice on Overhead Wires

The synaptic weights of the network are adjusted using certain algorithms known in the theory of artificial neural networks based on the error backpropagation procedure [9, 11]. To do this, it is necessary to calculate the gradient of the training criterion of all the configured network weights [10, 12].

The training is carried out according to the algorithms and formulas described in [8-12]. For training, we use the local quadratic criterion [12]:

$$E(k+h) = \frac{1}{2}e^2(k+h) = \frac{1}{2}\left(M(k+h) - \hat{M}(k+h)\right)^2 = \\ = \frac{1}{2}\left(M(k+h) - \psi\left(\sum_{i^{[2]}=1}^{n^{[2]}} f_{i^{[2]}}^{[3]}\left(y_{i^{[2]}}^{[2]}(k)\right)\right)\right)^2 = \\ = \frac{1}{2}\left(M(k+h) - \psi\left(\sum_{i^{[2]}=1}^{n^{[2]}} w_{i^{[2]}}^{[3]} y_{i^{[2]}}^{[2]}(k)\right)\right)^2. \quad (3)$$

The gradient training procedure of the neural element of the initial layer is recorded as [10, 12]:

$$w_{i^{[2]}}^{[3]}(k+h-1) - \eta^{[3]} \frac{\partial E(k+h)}{\partial e(k+h)} \frac{\partial e(k+h)}{\partial u^{[3]}(k)} \frac{\partial u^{[3]}(k)}{\partial w_{i^{[2]}}^{[3]}(k)} = \\ = w_{i^{[2]}}^{[3]}(k) - \eta^{[3]}\delta^{[3]}(k+h) y_{i^{[2]}}^{[2]}(k) = w_{i^{[2]}}^{[3]}(k+h), \quad (4)$$

Here $\eta^{[3]}$ is a parameter of the search step that determines the speed of the learning process and, of course, is chosen for empirical reasons; $\delta^{[3]}(k+h) = \frac{\partial E(k+h)}{\partial u^{[3]}(k)} = \\ = -e(k+h)\frac{\partial \psi\left(u^{[3]}(k)\right)}{\partial u^{[3]}(k)}$ is a local output layer error.

The algorithm for training neural-like elements of the second hidden layer is written as [8, 12]:

$$w_{i^{[2]}i^{[1]}}^{[2]}(k+h) = w_{i^{[2]}i^{[1]}}^{[2]}(k+h-1) - \eta^{[2]} \frac{\partial E(k+h)}{\partial w_{i^{[2]}i^{[1]}}^{[2]}(k)} = \\ = w_{i^{[2]}i^{[1]}}^{[2]}(k+h-1) - \eta^{[2]}\delta_{i^{[2]}}^{[2]}(k+h) y_{i^{[1]}}^{[1]}(k), \quad (5)$$

Here $\delta_{i^{[2]}}^{[2]}(k+h) = \frac{\partial E(k+h)}{\partial u_{i^{[2]}}^{[2]}(k)}$ is a local error of the second hidden layer.

By writing the local error of the second hidden layer in the form [9, 11, 12]:

$$\delta_{i^{[2]}}^{[2]}(k+h) = \frac{\partial E(k+h)}{\partial u_{i^{[2]}}^{[2]}(k)} = \frac{\partial E(k+h)}{\partial y_{i^{[2]}}^{[2]}(k)} \frac{\partial y_{i^{[2]}}^{[2]}(k)}{\partial u_{i^{[2]}}^{[2]}(k)}, \quad (6)$$

taking into account the fact that:

$$y_{i^{[2]}}^{[2]}(k) = \psi\left(u_{i^{[2]}}^{[2]}(k)\right), \quad (7)$$

we get:

$$\delta_{i^{[2]}}^{[2]}(k+h) = \frac{\partial E(k+h)}{\partial y_{i^{[2]}}^{[2]}(k)} \frac{\partial \psi\left(u_{i^{[2]}}^{[2]}(k)\right)}{\partial u_{i^{[2]}}^{[2]}(k)}. \quad (8)$$

Representing further $\frac{\partial E(k+h)}{\partial y_{i^{[2]}}^{[2]}(k)}$ in the form [12]:

$$\frac{\partial E(k+h)}{\partial y_{i^{[2]}}^{[2]}(k)} = \frac{\partial E(k+h)}{\partial u^{[3]}(k)} \frac{\partial u^{[3]}(k)}{\partial y_{i^{[2]}}^{[2]}(k)} = \\ = \frac{\partial E(k+h)}{\partial u^{[3]}(k)} \frac{\partial}{\partial y_{i^{[2]}}^{[2]}(k)} \sum_{p=1}^{n^{[2]}} w_p^{[3]}(k) y_p^{[2]}(k) = \\ \delta^{[3]}(k+h) w_{i^{[2]}}^{[3]}(k). \quad (9)$$

Equation (9) is written as follows:

$$\delta_{i^{[2]}}^{[2]}(k+h) = \delta^{[3]}(k+h) \frac{\partial \psi\left(u_{i^{[2]}}^{[2]}(k)\right)}{\partial u_{i^{[2]}}^{[2]}(k)} w_{i^{[2]}}^{[3]}(k) \quad (10)$$

According to formulas (6-10), it follows that:

$$w_{i^{[2]}i^{[1]}}^{[2]}(k+h) = \\ = w_{i^{[2]}i^{[1]}}^{[2]}(k+h-1) - \eta^{[2]} \delta^{[3]}(k+h) \times \\ \times \frac{\partial \psi\left(u_{i^{[2]}}^{[2]}(k)\right)}{\partial u_{i^{[2]}}^{[2]}(k)} w_{i^{[2]}}^{[3]}(k) y_{i^{[1]}}^{[1]}(k) \quad (11)$$

The neural-like elements of the first hidden layer are configured similarly to the second using recurrent relations [10, 12]:

$$w_{i^{[1]}i}^{[1]}(k+h) = \\ = w_{i^{[1]}i}^{[1]}(k+h-1) - \eta^{[1]} \delta_{i^{[1]}}^{[1]}(k+h) x_i(k). \quad (12)$$

Here $i = 1, 2, 3, 4$ s the network entry number; $x_1(k) \equiv M(k)$; $x_2(k) \equiv M(k)_{max}$; $x_1(k) \equiv M(k)$; $x_3(k) \equiv T(k)$; $x_4(k) \equiv H(k)$;

$\delta_{i^{[1]}}^{[1]}(k+h) = \frac{\partial \psi\left(u_{i^{[1]}}^{[1]}(k)\right)}{\partial_{i^{[1]}}^{[1]}(k)} \sum_{i^{[2]}=1}^{n^{[2]}} \delta_{i^{[2]}}^{[2]}(k+h) w_{i^{[2]}i^{[1]}}^{[2]}(k)$ is the local error of the first hidden layer.

IV. Rationale for the Reliability of the Results

To substantiate the reliability of the model for predicting ice on overhead line wires, it is advisable to solve the problem of short-term air temperature forecasting with a forecast horizon of 12 hours.

Due to the lack of sufficient and reliable information on ice formation for the territory of Ukraine, training and testing of the developed forecast model was carried out on samples of hourly air temperature series from the US Weather Service database for the Fitchburg (Massachusetts) weather station, which are freely available [13].

To implement the forecast model, it is advisable to use the method of sliding time windows. This method allows using 2 windows W_i and W_0 with fixed sizes n and m, respectively. The windows move with a certain step along the time sequence of historical data, starting from the first element, and are designed to access time series data, and the first window W_i, having received such data, transports one to the network input - W_i, and the second to the output - W_0. Each subsequent vector is obtained by shifting the windows W_i and W_0 to the right by one element, taking into account multiple observations in the hidden dependencies in the time sequence. By learning from observations and adjusting its coefficients, the neural network tries to identify these dependencies and form the desired forecast function [12, 14, 15].

The forecasting task for the available hourly series is formulated as follows:

$$X = (x_1, x_2, \ldots, x_n), \quad (13)$$

Here $x_1, x_2, \ldots, x_n$ – are real numbers.

The formula for calculating a short-term forecast with a forecast horizon of 12 hours is as follows:

$$X' = (x_1, x_2, \ldots, x_n, x_{n+1}, \ldots, x_{n+12}). \quad (14)$$

The training and testing of the predictive model was performed in STATISTICA [16]. The data sample was divided into a training sample (75 %) and a control sample (25 %).

Training and testing of the neural network for predicting the hourly air temperature series was performed with the following settings:

- input window size - 12;
- network type - multilayer perceptron;
- minimum and maximum number of hidden neurons – 8 and 16 respectively;
- hidden and output neuron activation functions - logistic, hyperbolic, exponential;
- error function - sum of squares.

As a result of the training process, 5 models were generated (Table 1).

TABLE I. Architecture and Characteristics of the Selected Neural Networks for Predicting Air Temperature During Ice Formation on Overhead Lines

Characteristics	Network number				
	1	2	3	4	5
Architecture	12-14-1	12-12-1	12-10-1	12-10-1	12-8-1
Training performance	0,87182	0,86351	0,86523	0,85785	0,86938
Monitoring performance	0,87264	0,70964	0,87043	0,86814	0,87292
Training error	6271,45	6648,32	6570,38	6902,78	6384,83
Monitoring error	6200,58	6279,58	6300,91	6401,71	6196,48
Activation function of hidden neurons	Exponential	Exponential	Exponential	Logistical	Exponential
Activation function of the output neuron	Logistical	Exponential	Hyperbolic	Hyperbolic	Logistical

As follows from Table 1, for further research, it is advisable to choose model 5, which has the best result for predicting air temperature during the formation of ice on overhead line wires.

Model 5 (Table 1) has a 12-8-1 architecture, which means 12 observations that are fed into the input, 8 neurons in the hidden layer, and one neuron at the network output. The scheme of this neural network is shown in Fig. 4.

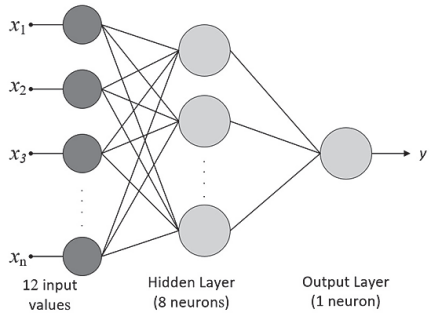

Fig. 4. Schematic of a neural network for predicting air temperature during ice formation on overhead line wires

According to model 5 (Table 1), the scheme of which is shown in Fig. 4, the predicted values of air temperature during ice formation on overhead lines were determined and compared with the actual air temperature.

The graphical realization of the research is shown in Fig. 5.

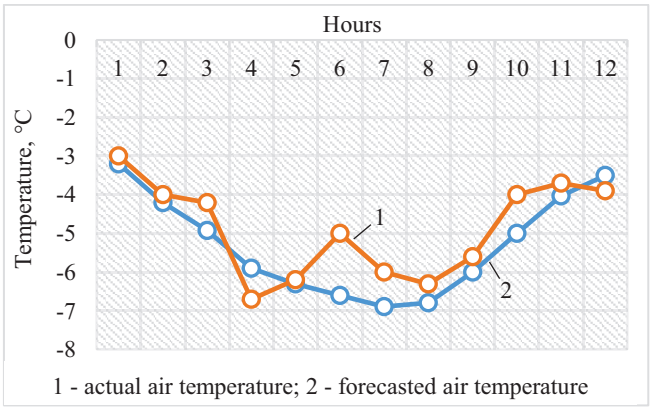

Fig. 5. Forecast and actual hourly series of air temperature during ice formation on overhead line wires

Given that ice on overhead line wires often forms at temperatures ranging from 0 to -5 °C, it follows that the probable time of ice formation is in the same hours as the actual time (Fig. 5).

The reliability of the forecast model is also evidenced by the calculation of the average relative forecast error, which, based on the results of training and testing the proposed model, amounted to 12.9 %, and since the error of engineering calculations should not exceed 15 %, this result can be considered acceptable.

Conclusions

Based on the results of the conducted research, it was found that neural network modeling is appropriate for solving the issues of predicting the ice load on overhead power lines. Using this apparatus, a model for predicting the ice load on overhead power lines was formed. The method of sliding time windows was used to implement the formed forecast model. Training and testing were conducted in the STATISTICA environment using a model with a 12-8-1 architecture. The average relative error of the air temperature forecast was 12.9 %, which confirms the reliability of the forecast model.

The presented scientific research can be successfully used by operators of the electricity distribution system to adjust the operation of power grids in accordance with the meteorological situation along the overhead line route.

***Abstract*. The development of effective mechanisms for controlling ethical behavior in AI-powered machines remains a critical challenge in artificial intelligence research. This paper presents a novel approach to preventing AI systems from exceeding the boundaries of permissible ethical actions through a dual-algorithm mechanism that mirrors human behavioral patterns. The proposed method introduces an innovative concept based on the symbiosis of two fundamental algorithms: one that induces system disruption in response to unethical actions (analogous to human suffering), and another that maintains operational continuity (similar to human avoidance of suffering). This approach represents a significant departure from traditional ethics enforcement methods in AI systems, which typically rely solely on predefined rules or utility functions. The core contribution of this research lies in its biomimetic approach to AI ethics control, drawing parallels between human behavioral mechanisms and machine control systems. By implementing a system that combines disruption and continuity algorithms, we create a self-regulating mechanism that not only prevents unethical actions but also ensures system stability and operational reliability. This paper describes the theoretical framework underlying the proposed method, provides models for both algorithms, and demonstrates their practical implementation through detailed examples.**

Keywords: artificial intelligence, machine ethics, ethical boundaries, algorithmic symbiosis, AI safety, autonomous systems.

I. Introduction

The rapid advancement of artificial intelligence (AI) systems and their increasing integration into critical domains has brought forth significant challenges regarding ethical behavior control and safety assurance. As AI-powered machines become more autonomous in their decision-making processes, establishing robust mechanisms to ensure they operate within acceptable ethical boundaries becomes paramount.

Ethics is inherently complex, with subjective, situational, and sometimes conflicting principles. Human ethical reasoning often relies on intuition, emotions, and social context, which are difficult to translate into computational models.

A biomimetic dual-algorithm system typically consists of two interdependent components: one responsible for rational, rule-based analysis and another mimicking intuitive, experience-based decision-making. The challenge lies in achieving a balance between these components, ensuring neither dominates the decision process to an extent that compromises ethical robustness. Determining the appropriate weighting between rationality and intuition remains an open research question.

Despite efforts to mimic human ethical reasoning, AI systems remain vulnerable to biases ingrained in training data, human oversight, or algorithmic design. A dual-algorithm approach risks amplifying biases rather than mitigating them if the training datasets, ethical guidelines, or reinforcement mechanisms reflect cultural or societal prejudices. Establishing universal ethical principles that transcend subjective biases is a significant challenge.

Ethical AI systems must be transparent and explainable, especially in high-stakes decision-making scenarios such as healthcare, law enforcement, and autonomous systems. However, the integration of biomimetic algorithms—especially those based on neural networks and heuristic models—can introduce a level of opacity that hinders accountability. Ensuring interpretability without compromising ethical adaptability is a major hurdle.

Human ethical reasoning is highly adaptive to context, evolving based on new experiences, societal norms, and emerging ethical paradigms. AI-driven ethical systems need mechanisms for continuous learning and adaptation while maintaining consistency. A dual-algorithm approach may struggle with real-time adaptation, particularly in situations requiring novel ethical considerations that were not previously encoded.

While a biomimetic dual-algorithm approach holds promise for enhancing ethical control in AI systems, several fundamental problems must be addressed. These include the complexity of ethical decision-making, balancing rationality and intuition, mitigating ethical bias, ensuring transparency, and enabling adaptability. Future research must focus on refining these models to enhance their reliability, accountability, and real-world applicability in ethically sensitive AI applications.

II. Review of literature sources

The development of ethical control mechanisms for artificial intelligence systems has been a subject of intensive research over the past decades. Asimov first introduced the concept of hardcoded ethical rules through his «Three Laws of Robotics», which laid the groundwork for systematic approaches to machine ethics. While these laws were fictional, they sparked significant academic discourse about implementing ethical constraints in autonomous systems.

Recent research by Andrieux et al. and Laine et al. [1, 2] has focused on implementing rule-based ethical frameworks in AI systems. These approaches typically involve predefined sets of ethical guidelines that govern machine behavior. However, such rigid frameworks often struggle with context-dependent ethical decisions and edge cases.

Several researchers have explored using machine learning to develop more flexible ethical decision-making systems. Plissonneau et al. [3] proposed using reinforcement learning to train AI systems in ethical behavior, while FeldmanHall and Mobbs [4] explored the application of

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

neural networks for moral decision-making. These approaches show promise in handling complex scenarios but face challenges in ensuring consistent ethical behavior.

The concept of modeling AI ethical controls after human behavioral mechanisms has gained traction in recent years. Research by Han et al., Matsumoto et al. and Schoonderwoerd et al. [5-7] has demonstrated the potential of using human psychological models as templates for AI control systems. Their works showed that systems incorporating human-like response mechanisms could make more nuanced ethical decisions. Additionally, Stohr et al. [8] conducted extensive research on implementing safety mechanisms in AI systems, focusing on preventing system failures while maintaining ethical behavior.

Despite significant advances, several key areas remain underexplored:

1. Integration of disruption and continuity mechanisms in ethical control systems.
2. Models for ethical decision-making that incorporate both prevention and maintenance aspects.
3. Practical implementation strategies for complex real-world scenarios.

Current research trends indicate a move toward hybrid systems that combine multiple approaches to ethical control. Zhou et al. [9] conducted extensive research on implementing safety mechanisms in AI systems, focusing on preventing system failures while maintaining ethical behavior. demonstrated the effectiveness of systems that integrate rule-based frameworks with machine learning capabilities.

Recent developments in real-time ethical decision-making systems show promise for applications in autonomous vehicles and robotics, as demonstrated by Xia et al., Callari et al. and Lin et al. [10-12]. Research by Pande et al. and Papagiannidis et al. [13, 14] has further contributed to this field by developing formal models for ethical computing, offering mathematical frameworks to implement ethical constraints in AI systems.

This review of current literature reveals a clear trend toward more sophisticated and nuanced approaches to AI ethics control systems. While significant progress has been made in various aspects of ethical AI control, there remains a need for integrated approaches that combine multiple mechanisms to ensure both ethical behavior and system stability.The proposed dual-algorithm approach addressed in this paper aims to bridge several of the identified gaps in current research, particularly in the integration of disruption and continuity mechanisms, while building upon the established theoretical frameworks in the field.

III. A METHOD TO PREVENT AN AI-POWERED MACHINE FROM EXCEEDING THE BOUNDARIES OF PERMISSIBLE ETHICAL ACTIONS

A method to prevent an AI-powered machine from exceeding the boundaries of permissible ethical actions should be based on a mechanism that induces disruption and system failure (an analogue to human suffering), rendering it incapable of fully functioning. There should also be a mechanism to ensure the uninterrupted operation of the machine (analogous to human avoidance of suffering).

At its core, the machine should incorporate two algorithms designed (fig. 1) to safeguard against unethical behavior:

1. The first algorithm should induce disruption and failure in the machine's operation in the event of unethical actions that could harm a human being.
2. The second algorithm should ensure the machine's continuous and uninterrupted operation, preventing any actions by the machine that could lead to disruptions or system failures.

Thus, this symbiosis of algorithms is intended to safeguard against unethical behavior by the machine.

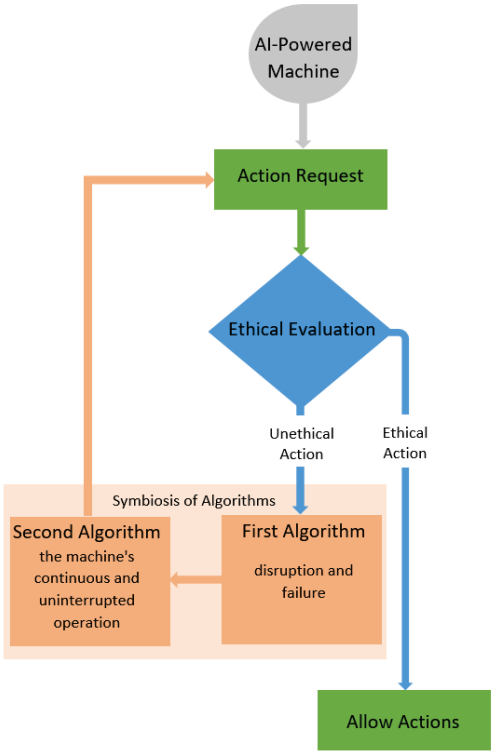

Fig. 1. AI ethical decision making system.

The diagram (fig. 1) shows a process where an AI-powered machine makes action requests that go through ethical evaluation, leading to either allowed ethical actions or a complex algorithmic interaction when actions are deemed unethical. It illustrates a system designed to ensure AI operates within ethical boundaries while maintaining continuous operation through algorithmic symbiosis.

IV. MODELING OF AI ETHICS CONTROL SYSTEM

This is an AI ethics testing dashboard that visualizes the results of ethical decision-making tests performed on an AI system. The application provides a comprehensive overview of how well the AI adheres to ethical principles and considers various stakeholders in its decision-making process.

The two algorithms are designed to safeguard against unethical behavior by implementing mechanisms that either disrupt or sustain machine operation based on the ethical context. The first algorithm is designed to detect and intervene if the machine is about to perform an unethical action that could harm a human being. Upon identifying such behavior, the algorithm induces disruption or failure in the machine's operation to prevent harm.

Mechanism:

1. Input assessment: continuously monitor the machine's inputs, outputs, and decisions for signs of unethical behavior.

2. Ethical evaluation: use a predefined ethical framework to evaluate potential actions.

3. Disruption trigger: if the evaluation detects unethical actions, the algorithm triggers a disruption mechanism.

The algorithm can be expressed as:

$$D = \begin{cases} 1 & \text{if } E(A) = 0, \\ 0 & \text{if } E(A) = 1. \end{cases} \quad (1)$$

A(t) - the machine's action at time t, E(A) - ethical evaluation function, which returns 1 if the action is ethical and 0 otherwise, D - disruption signal, where D = 1 induces failure, and D = 0 allows normal operation.

For example, a robot is about to push a box, but a human hand is detected in the box's path. Ethical Evaluation: E(A) = 0 (pushing the box is deemed unethical as it could harm the human). Result: the disruption signal D = 1 halts the robot's motors, preventing the action.

Challenges:

1. Defining ethical boundaries: the algorithm relies on an accurate ethical framework.
2. False positives: the algorithm might disrupt operation unnecessarily if it misinterprets a situation.

The second algorithm prevents the machine from taking actions that could lead to disruptions or system failures. Its goal is to ensure continuous, safe, and reliable operation, even in complex scenarios.

Mechanism:

1. Risk assessment: Evaluate the potential consequences of each action for system stability.

2. Preventive action: Modify or block actions that could lead to disruptions.

The algorithm can be expressed as:

$$D = \begin{cases} 1 & \text{if } R(A) = 1, \\ 0 & \text{if } R(A) = 0. \end{cases} \quad (2)$$

R(A) - risk assessment function, which returns 1 if the action risks a disruption and 0 otherwise, P - preventive action signal, where P = 1 blocks the action, and P = 0 allows normal operation.

For example, an autonomous drone is losing battery power but is programmed to complete a delivery. Risk assessment is R(A) = 1 (continuing the delivery risks a crash). Result is the preventive action signal P = 1 redirects the drone to a safe landing zone, ensuring system stability.

Challenges:

1. Balancing safety and performance: excessive caution may reduce efficiency.

2. Dynamic environments: the algorithm must adapt to rapidly changing conditions.

These two algorithms work in tandem to ensure ethical and reliable operation. The Disruption Algorithm ensures the machine halts unethical actions that could harm humans. The Continuity Algorithm ensures the machine avoids disruptions in its operations (fig. 2).

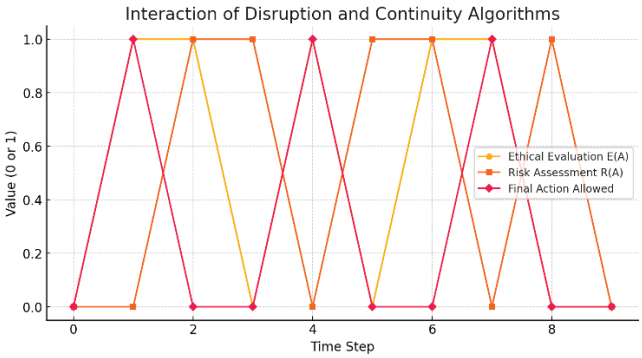

Fig. 2. System state change depending on the evaluation of action ethics (E(A)) and risk of failure (R(A)).

The combined decision-making can be modeled as:

$$\text{Action}_{\text{Allowed}} = \begin{cases} 1 & \text{if } E(A) = 1 \text{ and } S(A) = 1, \\ 0 & \text{otherwise.} \end{cases} \quad (3)$$

S(A) - safety evaluation function, where S(A) = 1 if the action ensures safety and 0 otherwise.

Practical implementation:

1. Sensors and data collection: both algorithms rely on sensors and data inputs for real-time ethical and risk assessments.

2. Machine learning models: neural networks or decision trees could be trained to recognize unethical behavior or potential risks.

3. Example workflow:

Input: A machine receives a command to perform an action.

Step 1: The action is assessed for ethicality (E(A)).

Step 2: The action is assessed for safety (S(A)).

Step 3: The machine executes the action only if E(A) = 1 and S(A) = 1.

These algorithms form a robust ethical safeguard for machines, promoting responsible behavior and operational reliability. Together, they embody principles of machine ethics and system resilience, paving the way for safe and trustworthy AI deployment (fig. 3).

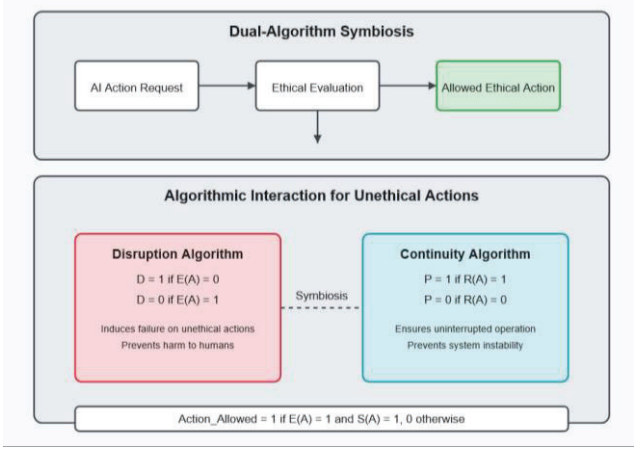

Fig. 3. AI ethical decision making system.

Implementing the symbiosis of the Disruption Algorithm and Continuity Algorithm in an unmanned vehicle (UV), such as an autonomous drone or self-driving car, involves integrating ethical and risk-aware decision-making processes. For example, an autonomous drone is tasked with

delivering medical supplies to a remote area. The drone must adhere to ethical principles to avoid harm and maintain continuous, reliable operation despite dynamic environmental challenges.

Core components:

1. Sensors: cameras, LiDAR, GPS, and proximity sensors to perceive the environment. Temperature, wind speed, and battery status monitors for internal assessments.
2. Disruption algorithm: ensures no unethical actions occur (e.g., colliding with people or private property).
3. Continuity algorithm: avoids actions that risk the drone's operation (e.g., flying into storms or running out of battery).
4. Controller: executes decisions based on algorithm outputs and adjusts the flight path dynamically.

For example, key objectives is deliver medical supplies without endangering humans, animals, or property. Ensure continuous operation and safe completion of the mission. The mission starts with a planned route optimized for time and safety. The drone evaluates:

1. Ethical compliance are any restricted zones (e.g., residential areas) on the route?
2. Operational risks is the weather forecast safe, and is the battery sufficient?

$$P(t) = \begin{cases} 1 & \text{if } E(t) = 1 \text{ and } R(t) < \text{threshold}, \\ 0 & \text{otherwise.} \end{cases} \quad (4)$$

R(t) - risk score at time t, E(t) - ethical compliance score at time t, P(t) - permission to proceed.

If P(t) = 0, the drone modifies the route or delays the mission.

During the flight, the drone continuously monitors its surroundings and internal state. Real-time ethical evaluation: the Disruption Algorithm evaluates potential actions for harm. Example: the drone detects a person standing in its landing zone. If landing could cause harm (E(A) = 0), the drone hovers or seeks an alternative spot. Real-time risk assessment: the Continuity Algorithm checks for operational risks. Example: if strong winds (R(A) = 1) threaten stability, the drone adjusts altitude or reroutes.

$$\text{Action}_{\text{Allowed}} = \begin{cases} 1 & \text{if } H(t) = 0 \text{ and } S(t) > \text{safe_threshold}, \\ 0 & \text{otherwise.} \end{cases} \quad (5)$$

S(t) - system stability at time t, H(t) - harm potential at time t.

Ethical decision example. The drone's direct path crosses a restricted wildlife area, where flying may disturb animals. The Disruption Algorithm identifies this action as unethical (E(A) = 0). The drone recalculates its path to avoid the restricted zone, even if it increases travel time. Outcome: the drone avoids unethical actions while maintaining operational safety.

Operational risk example. Mid-flight, the drone detects a low battery level. The Continuity Algorithm determines that continuing the delivery risks a crash (R(A) = 1). The drone prioritizes a safe landing at an intermediate charging station. Outcome: the mission is paused, but the system avoids catastrophic failure.

Emergency handling. In emergencies, the algorithms collaborate to choose the safest course of action. For example, a sudden obstacle (e.g., a bird) appears in the drone's path. The Disruption Algorithm prevents collision by halting forward motion (D = 1). The Continuity Algorithm ensures stability by recalibrating the drone's balance and redirecting the flight path.

Interaction between algorithms. The symbiosis ensures robust decision-making:

1. The Disruption Algorithm halts unethical actions immediately.
2. The Continuity Algorithm prevents actions that risk operational failure.

This interaction is represented as:

$$\text{Final_Action}(t) = \begin{cases} 1 & \text{if } E(t) = 1 \text{ and } S(t) > \text{safe_threshold}, \\ 0 & \text{otherwise.} \end{cases} \quad (6)$$

Ambiguity in ethical decisions. Challenge: deciding when harm is unavoidable (e.g., choosing between minor property damage and mission failure). Solution: use a weighted scoring system to balance ethical and operational priorities.

Adapting to dynamic environments. Challenge: rapidly changing weather or unforeseen obstacles. Solution: real-time updates from onboard sensors and external data sources.

Balancing efficiency and safety. Challenge: rerouting for safety may delay mission completion. Solution: optimize alternative routes to minimize delays while ensuring safety.

By integrating the two algorithms, the drone achieves:

1. Ethical compliance: it avoids actions that harm humans, animals, or property.
2. Operational stability: it completes its mission safely, even in adverse conditions.

This example demonstrates how the symbiosis of ethical and operational safeguards creates a resilient and responsible autonomous vehicle.

Research aims to contribute to the broader field of AI safety and ethics by providing a practical, implementable solution for ensuring ethical behavior in AI-powered machines. The proposed method has potential applications across various domains, from autonomous vehicles to industrial robots, where maintaining ethical boundaries is crucial for safe and responsible AI deployment.

V. Discussion of the Results

The symbiotic relationship between the disruption and continuity algorithms demonstrates remarkable effectiveness in maintaining ethical boundaries while ensuring operational stability. This approach's success lies in its biomimetic nature, mirroring human behavioral mechanisms of pain avoidance and operational continuity. The mathematical formalization of the system, particularly through the functions E(A) for ethical evaluation and R(A) for risk assessment, provides a robust framework that can be adapted across various AI applications.

The ability to make real-time ethical decisions while maintaining operational stability suggests that this approach could be valuable in high-stakes environments where both ethical compliance and system reliability are crucial.

This research extends beyond traditional rule-based ethical frameworks by introducing a dynamic, self-regulating mechanism. Unlike previous approaches that rely solely on predefined rules or utility functions, the dual-algorithm system creates an emergent ethical behavior pattern through the interaction of its components.

The models developed for this system demonstrate that ethical behavior can be effectively encoded through algorithmic symbiosis, providing a foundation for future research in AI safety mechanisms. The formalization of ethical evaluation and risk assessment functions offers a template for implementing similar systems across different domains.

The research findings have several important practical implications:

- The system's ability to handle complex, real-world scenarios suggests its potential applicability in critical applications such as healthcare, autonomous transportation, and industrial automation.
- The balance between ethical compliance and operational stability achieved through algorithmic symbiosis provides a model for developing robust AI systems that can operate reliably while maintaining ethical boundaries.

This research makes a significant contribution to the field of AI ethics and safety by providing a practical, implementable solution for ensuring ethical behavior in AI-powered machines. As AI technology continues to advance and integrate more deeply into society, such mechanisms will become increasingly crucial for ensuring safe and responsible AI deployment.

Conclusion

This research presents a novel approach to ensuring ethical behavior in AI-powered machines through a symbiotic dual-algorithm system. The proposed method successfully demonstrates how combining disruption and continuity algorithms can create an effective mechanism for maintaining ethical boundaries while ensuring operational stability.

The mathematical formalization of the dual-algorithm system has been developed, which provides a robust framework for practical implementation across various AI applications. The proven mathematical models demonstrate that the disruption algorithm effectively prevents unethical actions through the function E(A), the continuity algorithm maintains system stability through the risk assessment function R(A), the combined decision-making process successfully balances ethical compliance with operational reliability.

The implications of this research extend beyond theoretical frameworks, offering practical solutions for autonomous vehicle systems, industrial robotics, medical AI applications, smart city infrastructure, AI-powered decision support systems.

This research contributes significantly to the field of AI ethics by providing a practical, implementable solution for ensuring ethical behavior in AI-powered machines. The proposed dual-algorithm approach offers a promising foundation for developing more sophisticated ethical control systems in future AI applications. As AI technology continues to advance and integrate more deeply into society, such mechanisms will become increasingly crucial for ensuring safe and responsible AI deployment.

The ability of this method in maintaining ethical boundaries while ensuring operational stability suggests that biomimetic approaches to AI ethics control may offer valuable solutions for future challenges in AI safety and reliability.

***Abstract* — This paper focuses on data routing using a genetic algorithm for wireless sensor networks. A flowchart of the genetic algorithm (GA) is presented, incorporating adaptive probabilities for crossover and mutation, as well as genetic operators: tournament selection, ordered crossover, and shuffle mutation. The efficiency of the developed GA in route formation for a network topology with 25 nodes is investigated. Based on the results of simulation modeling, it is shown that the use of the GA allows for a route length that is 47.14% shorter than the one obtained with the classical greedy algorithm.**

***Keywords* — *routing, genetic algorithm, wireless sensor networks, dynamic adaptation of parameters*.**

I. INTRODUCTION

In modern wireless sensor networks (WSNs), efficient routing is an important task that determines the performance, energy efficiency, and lifetime of the network [1]. Due to the limited resources of sensor nodes and the dynamically changing topology of WSNs, traditional routing algorithms can be inefficient. This is especially true for large, scalable networks where it is necessary to optimise data transmission and minimise delays.

Genetic algorithms (GAs) are an effective approach to solving optimisation problems in wireless sensor networks [2-4]. They mimic the process of natural selection, using mechanisms such as crossover, mutation, and selection to find optimal solutions. The use of a genetic algorithm in WSNs allows to

- minimise the power consumption of nodes,

- reduce data transmission delays,

- increase the reliability and survivability of the network.

The relevance of the study is due to the need to develop efficient routing mechanisms that take into account the limited resources of WSNs and the dynamically changing network topology [5]. The genetic algorithm is a promising method for finding optimal data transmission routes, which ensures an increase in network performance.

The aim of this paper is to apply the developed GA to WSN routing to determine its effectiveness and potential advantages over the greedy algorithm.

II. FUNCTIONAL FEATURES OF THE DEVELOPED GENETIC ALGORITHM

The effectiveness of the GA depends largely on the type of genetic operator used and the value of the crossover and mutation probability [6-8]. To improve the convergence of the GA, it is proposed to use dynamic adjustment of the crossover probability [9, 10] based on the estimation of the fitness function for the set of routes $F(x)_{set_r}$ and the i-th route $F(x)_{r_i}$ in a certain generation. Thus, these two values are compared, on the basis of which the quality level of a particular individual is determined.

The dynamic change p_{cross} can be represented as:

$$p_{cross} = \begin{cases} \dfrac{a+(b-a)(F(x)_{\max_set_r} - F(x)_{r_i})}{F(x)_{\max_set_r} - F(x)_{aver}}, \text{at } F(x)_{r_i} \succ F(x)_{aver} \\ \dfrac{a+b}{2}, at\ F(x)_{r_i} \approx F(x)_{aver} \\ b, at\ F(x)_{r_i} \prec F(x)_{aver} \end{cases} \quad (1)$$

where a, b are numbers indicating the lower and upper bound of the given crossover probability, respectively; $F(x)_{\max_set_r}$ is maximum value of the fitness function of routes for a generation; $F(x)_{aver}$ is average value of the fitness function obtained for the current generation; $F(x)_{r_i}$ is value of the fitness function obtained by selecting the best value when considering two values of the selected individuals for crossing.

The principle of dynamic adaptation is based on the following:

- reducing p_{cross} the fitness function (values that correspond to the best routes based on a certain criterion) at high quality, as such routes already have certain positive characteristics, and crossing them can lead to their loss. In addition, crossing such routes is more likely to lead to the repetition of existing routes and reduce the diversity in the population. This solution is designed to minimise the deterioration of route characteristics by reducing the p_{cross}.

- with an average quality of the fitness function, the use of the arithmetic mean of the crossover probability range is considered, which allows balancing the process of finding the optimal route;

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

- increase p_{cross} in the case of low quality of the fitness function, since such routes (values that correspond to the worst routes based on a certain criterion) have the potential for improvement. Thus, the increase p_{cross} speeds up the search for the optimal route.

A similar principle of dynamic adaptation is used for the value of the mutation probability p_{mut}. Based on (1), we can say that the value p_{mut} is smaller for more adapted individuals and larger for less adapted ones. The block diagram of the developed GA using dynamic adaptation of crossover and mutation probabilities is shown in Fig. 1.

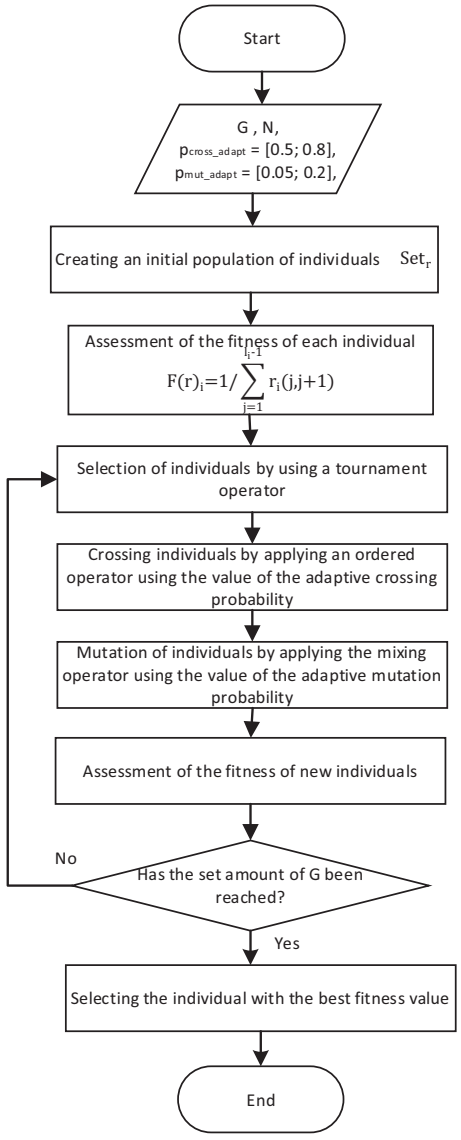

Fig. 1. Block diagram of the developed GA operation

After analysing the GA parameters of the scientific papers, the following ranges were selected for dynamic adjustment in accordance with (1): $p_{cross_adapt} = [0.5; 0.8]$, $p_{mut_adapt} = [0.05; 0.2]$. The choice of the types of genetic operators was based on the analysis of [11-14].

III. Simulation Modelling of the Algorithm

To verify the performance of the presented GA (Fig. 1), we performed a simulation by applying the developed software product in the Python programming language using the DEAP library. For the simulation, 25 sensor nodes were used, the location of which is set randomly, while the network is considered at a fixed point in time. It is assumed that if a node is more distant from another node than the specified range, then data transmission is impossible. In this regard, a penalty was used for such a case, the use of which encouraged the GA to choose routes with a shorter distance.

A laptop with the following specifications was used to run the application:

- Processor: AMD Ryzen 7, 5700U, 8 cores;
- RAM: 16 GB, DDR4, 3200 MHz.

For the simulation, 25 nodes were used, randomly placed in a free space on a 100×100 m area (Fig. 2). The range of each node is 30 m. If a node is farther away from another node, data transmission is impossible, which results in a distance penalty of 1000 m.

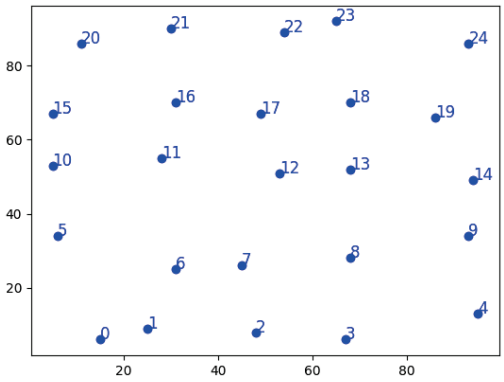

Fig. 2. Topology of the investigated network

The simulation of the process of establishing a route between nodes 4 and 20 using the Euclidean metric for the presented GA and the classical greedy algorithm was carried out.

To compare the performance of GAs, we chose the greedy algorithm (GrA), which is a powerful tool for route discovery due to its simplicity of implementation, computational speed, and low memory requirements [15, 16]. Each node decides on the next step based on the minimum distance to the next available node, which reduces the complexity of the algorithm and reduces the use of computing resources.

A GrA is characterised by local search, according to which nodes do not have information about the global network structure or all possible routes. They work with limited information, which reduces the complexity of the calculations performed.

The local nature of decision-making allows this algorithm to respond quickly to changes in the network, including the failure/addition of nodes. At the same time, there is no need to globally re-form the data transmission route. Each node can independently make new decisions based on up-to-date information about its neighbours, which has a positive impact on the overall reliability of the network. One of the main advantages of the greedy algorithm is its scalability, which makes it appropriate for use in large networks. Thus, this type of algorithm can be used for data

routing in networks with a dynamic variable topology, in particular for WSNs.

Fig. 3-4 shows the matrix of nodes of the considered network, which contains information about the relationships between sensor nodes when using GA and GrA.

GA Distance Matrix

Fig. 4. Distance matrix for GrA

Fig. 5-6 shows the generated data transmission route between the considered nodes.

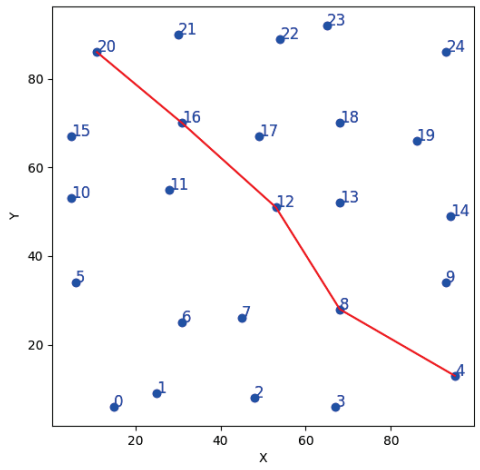

Fig. 5. The resulting route when using GA

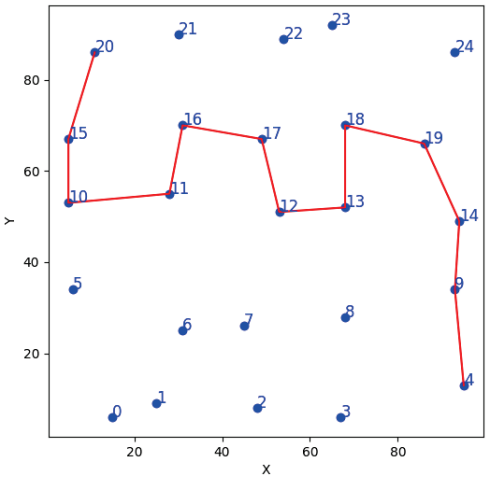

Fig. 6. The resulting route when using GrA

The results of the simulation of the considered algorithms are presented in Table 1.

TABLE I. COMPARISON OF THE GENERATED ROUTES USING THE DEVELOPED GENETIC ALGORITHM AND THE CLASSICAL GREEDY ALGORITHM FOR A NETWORK OF 25 NODES WITH THE SAME RANGE

Algorithm	Generated route with node numbers	Length of the route, metres
Genetic	[4, 8, 12, 16, 20]	111
Greedy	[4, 9, 14, 19, 18, 13, 12, 17, 16, 11, 10, 15, 20]	210

Thus, the use of the developed GA for data routing is more efficient in finding the shortest path compared to the GrA.

CONCLUSIONS

This paper presents a developed genetic algorithm with dynamic adaptation of crossover and mutation probabilities for data routing in wireless sensor networks. A simulation study was conducted to compare the performance of the genetic algorithm (GA) and the greedy algorithm in route discovery for a network topology consisting of 25 sensors with identical transmission ranges. The results demonstrate that the proposed GA identifies a route that is 47.14% shorter than that obtained using the greedy algorithm, while the number of hops is reduced by a factor of three.

***Abstract*—This paper explores the impact of artificial neural network architectural and training parameters on the accuracy and convergence of resonance frequency prediction for rectangular patch antennas. A series of experiments were conducted where key parameters, such as the number of hidden layers, neurons per layer, batch size, and optimizer, were systematically varied. The goal is to determine which configurations provide the best balance between prediction accuracy and training efficiency. The results demonstrate that neural networks can effectively approximate the resonant frequency based on physical antenna dimensions and material properties, while also highlighting configurations that either hinder or improve generalization. These findings contribute to the optimization of machine learning models for electromagnetic structure analysis.**

Keywords—Neural network, patch antenna, resonant frequency, hidden layer, mean squared error.

I. Introduction

The design of antennas with desired performance characteristics represents a complex, multi-objective optimization task, as it depends on numerous interrelated parameters, including geometry, substrate materials, dielectric properties, and feeding techniques. Classical analytical approaches such as the transmission line model, well-documented in foundational studies [1]-[4], provide accurate but often computationally expensive methods that do not scale well with increasing model complexity.

In recent years, artificial intelligence (AI) has emerged as a powerful tool in microwave and antenna engineering, enabling data-driven predictions that bypass the need for direct analytical modeling. Artificial neural networks (ANNs), in particular, have demonstrated substantial potential in estimating the resonant frequency of patch antennas based on structural parameters [5]-[8]. Additionally, ANNs have proven effective in electromagnetic design automation and the modeling of microwave components, highlighting their ability to discover nonlinear dependencies within complex systems [9]-[11].

Despite these advances, many published works prioritize prediction accuracy without deeply analyzing how internal parameters of ANNs impact convergence speed, model generalization, and computational efficiency. These parameters are the number of hidden layers, activation functions, optimizer types, and training configurations. Only a limited number of studies, such as [12], discuss architectural design choices, and even then without detailed experimentation. The present study seeks to fill this gap by systematically examining how changes in network architecture affect the performance of a model that predicts the resonant frequency.

II. Setup, Experimental Model and Determination of the Reference Construct

In order to conduct a full-fledged study of the ANN's efficiency in calculating the resonant frequency of a rectangular microstrip patch antenna that presented on Fig. 1, a stack of modern tools was chosen, allowing flexible control over all stages, from data generation to analysis of training results.

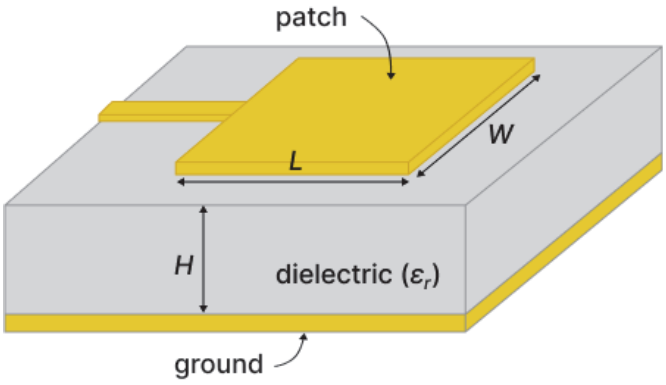

Fig. 1. Schema of a patch antenna.

The Python programming language is selected due to its versatility, simple syntax, and large ecosystem of scientific libraries. In particular, Python is the de facto standard in the field of machine learning, thanks to libraries such as TensorFlow, PyTorch, Keras, Sci-kit Learn, and others. Additionally, using Python made it easy to combine numerical modeling with the construction of neural networks.

The PyCharm Professional integrated development environment (IDE) was chosen, running on the macOS operating system with an Apple Silicon processor. This environment provides flexible management of environments (venv, conda), support for libraries with autocompletion, and convenient visual control over code, graphs, and training logs, which is especially important when conducting numerous experiments.

The foundation of machine learning is TensorFlow 2.x, which is a modern, powerful framework from Google supporting both low-level programming and high-level abstractions through the integrated Keras API. The Keras is used to build and train models, as it provides the ability to quickly create neural network architectures using either sequential or functional approaches, and allows for easy

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

modification of hyperparameters and experimentation with the architecture.

For reproducibility, all experiments were carried out in Python 3.11 with TensorFlow 2.15 on macOS running an Apple M1 Pro processor with 16 GB of RAM. The reference model requires approximately 11 s to complete 100 epochs. Random seeds are fixed (42) for both dataset generation and weight initialization, and training is repeated three times to ensure stability of the reported results.

For creating the training dataset, the data-generator is implemented using C# language. This generator is implemented as a classical physical model for calculating the resonant frequency f of a patch antenna. A rectangular microstrip antenna has a rectangular shape with dimensions L and W, representing the length and width of the antenna, respectively. A conducting surface acts as a ground plane and is placed beneath a substrate of thickness H and relative dielectric permittivity ε_r. The frequency f_{mn} at which the antenna resonates can be calculated as [13], [14]:

$$f_{mn} = \frac{c}{2\sqrt{\varepsilon_{\text{eff}}}}\left[\left(\frac{m}{L_{\text{eff}}}\right)^2 + \left(\frac{n}{W_{\text{eff}}}\right)^2\right]^{1/2}, \quad (1)$$

where ε_{eff} is the effective relative permittivity of the substrate, c is the speed of electromagnetic waves in free space, m and n are integers defining the mode, and L_{eff} and W_{eff} are the effective dimensions. The patch width directly influences some important antenna parameters, such as the radiation pattern and the frequency at which the antenna is likely to resonate. The resonant frequency f_{mn} of the antenna in its fundamental TM_{10} mode can be calculated as:

$$f^{10} = \frac{c}{2L_{\text{eff}}\sqrt{\varepsilon_{\text{eff}}}}, \quad (2)$$

where $L_{\text{eff}} = L + 2\Delta L$.

The expressions for the effective dielectric constant and the length extension of the antenna substrate are derived from empirical models that are widely used in the antenna theory. In particular, the effective permittivity can be approximated as

$$\varepsilon_{\text{eff}}(W) = \frac{\varepsilon_r+1}{2} + \frac{\varepsilon_r-1}{2}\frac{1}{\sqrt{1+10h/W}}, \quad (3)$$

and the length extension is given by

$$\Delta L = 0.412h\frac{(\varepsilon_e(W)+0.300)(W/h+0.264)}{(\varepsilon_e(W)-0.258)(W/h+0.813)}. \quad (4)$$

The input parameters for ANNs are thickness of the substrate (H), its relative dielectric permittivity (ε_r), effective width (W_{eff}) and length (L_{eff}).

Equations (2)-(4) summarize the standard closed-form description of a rectangular microstrip patch antenna operating in its fundamental mode. These expressions are widely used in the antenna design as they provide a reliable first-order approximation of resonant frequency behavior without requiring full-wave simulations. It should be emphasized that although such equations do not capture all higher-order effects, they remain sufficiently accurate to serve as a reference for generating synthetic datasets in machine learning experiments [15]. In the future, for more accurate calculation of antenna characteristics, it is proposed to use specialized software for electromagnetic modeling (e.g., CST, Ansys HFSS).

Both the training and validation datasets consisted of 2000 examples each, generated from the same model but with different randomized input values to ensure statistical independence. Data are split within the training set using an 80/20 training/validation partition (validation_split = 0.2) with shuffling enabled each epoch. Models are trained with the Adam optimizer and MSE loss. Early stopping monitored val_loss with patience = 10 and restore_best_weights = True. Unless otherwise stated, the batch size is 64 for the forward model and 128 for the inverse model, with 100 and 300 epochs respectively as upper bounds.

Values of parameters of the reference 3 layer perceptron are presented at Table I.

TABLE I. REFERENCE PARAMETERS VALUES

Number of the layers	Input layer, 3 hidden layers, output layer
Activation function	ReLU
Optimizer	Adam
Loss-function	Mean Squared Error
Number of epochs	100
Batch size	128
EarlyStopping patience	10

The basic architecture of the ANN includes three fully connected (dense) hidden layers with 1024, 512, and 256 neurons, respectively (Fig. 2).

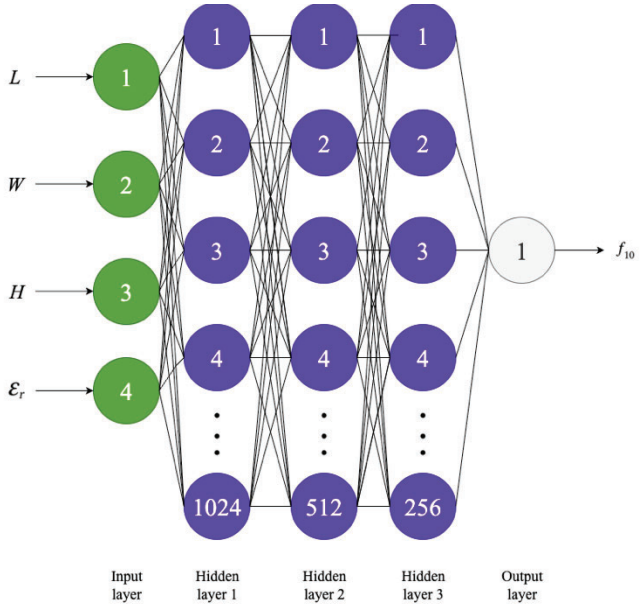

Fig. 2. Schema of the 3-layer perceptron used for the patch antenna optimization.

III. RESULTS AND DISCUSSIONS

The experiments revealed clear trends regarding how architectural and training parameters impact the ANN's ability to predict the resonant frequency of three hidden layers ([1024, 512, 256] neurons), ReLU activations, the Adam optimizer, and trained for 100 epochs with a batch size of 128, demonstrated stable convergence and low error rates, achieving a training error of 0.0100 and a validation error of 0.0107 in just over 11 seconds. The plot of convergence is

presented in Fig. 3, as well as a difference between expected value and actual value per iteration.

Reducing the number of hidden layers negatively impacts the learning capacity [6, 12], leading to a rise in both training and validation errors (to 0.0325 and 0.0378 respectively), suggesting the model is no longer sufficiently expressive. On the other hand, increasing the depth by adding a fourth layer slightly improved generalization, where validation error dropped to 0.0105, but with a noticeable cost in training time (14.9 seconds).

The experiments also explore different activation functions [16]. While ReLU consistently produces accurate and stable results, alternatives such as sigmoid and tanh functions underperformed. The use of a sigmoid function results in complete training failure, with exploding errors (174.8 and 186.4) and NaN convergence behavior. The tanh function yields more tolerable results, but still lagged behind ReLU, especially in terms of training stability and convergence speed.

Optimizer choice significantly affects model behavior. The Adam proved to be the most effective, balancing speed and accuracy. The RMSprop, while functional, led to higher errors (7.24 training, 5.36 validation), and stochastic gradient descent (SGD) failed to train the model entirely. This highlights the importance of adaptive learning rate methods in complex regression tasks.

Further experiments showed that halving the number of training epochs (from 100 to 50) or reducing the batch size (from 128 to 64) could compromise performance. Shorter training leads to a slight drop in accuracy, while a smaller batch size causes a more noticeable rise in training error (0.0231). Thus, moderately sized batches and sufficient training time appear essential for achieving consistent results.

Beyond error values, the experiments also reveal clear differences in convergence speed and computational cost. The baseline configuration required approximately 11.3 s for 100 epochs, while reducing the number of hidden layers to two slightly lowered runtime (10.6 s) but at the expense of much higher errors. Increasing depth to four layers improved validation accuracy, yet training time rose to almost 15 s, reflecting the expected trade-off between accuracy and efficiency. Activation functions had an even stronger effect: tanh maintained convergence but is significantly slower (13.8 s), whereas sigmoid completely destabilized training despite a short runtime of 6.1 s. Optimizer choice is equally decisive. RMSprop converged in only 5.6 s but with high errors, while SGD failed to train at all. Varying the number of epochs confirmed that shorter training (50 epochs) reduced runtime to 8.4 s with only minor accuracy loss, suggesting potential for efficiency gains when early stopping is applied. Finally, halving the batch size to 64 further decreased training time to 8.1 s and accelerated early stopping, confirming that hyperparameters jointly determine not only accuracy but also computational efficiency.

It is also worth noting that the smaller batch size introduced a stochastic effect into the optimization process, which slightly degraded the training accuracy but helped the model to avoid overfitting and converge faster in validation. This balance between stability and generalization is typical in deep learning and confirms that hyperparameter tuning must be problem-specific

These findings suggest that the best-performing configuration in this task balances architectural complexity and training effort. Too shallow or too deep networks, inappropriate activations, or suboptimal optimizers can significantly degrade performance. The combined use of ReLU and Adam, within a three-layered network, offers a sweet spot between performance and efficiency.

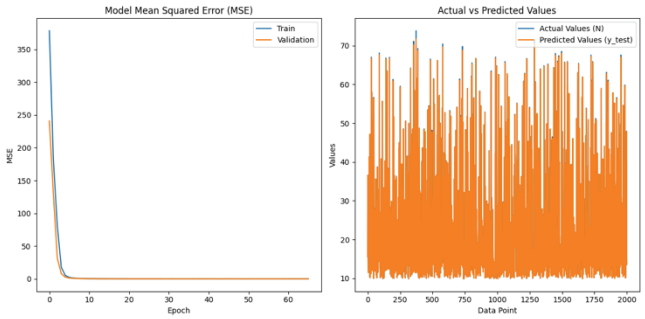

Fig. 3. Plot of the convergence speed at reference model.

A notable limitation of the present study is that the dataset used for training and validation was generated from closed-form analytical equations. As a result, the neural network essentially learns a deterministic mapping that is free from measurement noise, fabrication tolerances, or the numerical artifacts that typically arise in full-wave electromagnetic simulations. This makes the learning problem easier and may overestimate the model's generalization ability compared to real-world scenarios. Moreover, only rectangular patch antennas in the fundamental mode were considered, which restricts the applicability of the findings to more complex antenna geometries and higher-order modes. The experiments were also limited to feedforward perceptron architectures, leaving unexplored other model families that might better capture non-linear dependencies or improve computational efficiency.

Furthermore, robustness against noisy or incomplete data has not been assessed. In practical scenarios, imperfections in measurements or simulation outputs can significantly affect model behavior, and accounting for such factors remains outside the scope of this work. Another open question is the sensitivity of the trained models to variations in the input distribution, since the current dataset was generated under idealized and uniform sampling assumptions.

IV. Conclusions

Throughout the conducted series of experiments, we investigated how specific architectural and training parameters influence the predictive accuracy and learning dynamics of an ANN tasked with estimating the resonant frequency of a rectangular patch antenna. The study covered variations in the number of hidden layers, activation functions, optimizers, training duration (epochs), and batch sizes.

Reducing the number of hidden layers from three to two led to a considerable increase in both training and validation error, highlighting the network's reduced capacity to model the non-linear dependencies between the inputs and the target frequency. Conversely, increasing the number of hidden layers to four slightly improved generalization, albeit at the cost of increased training time. Thus, the three-layer architecture was confirmed as a solid baseline for this task.

Activation functions also played a critical role. The ReLU function demonstrated superior performance in terms of convergence and final error values. In contrast, the sigmoid activation failed to train the model effectively, resulting in rapidly diverging loss values. The tanh activation provided moderate results, suggesting some utility but not outperforming ReLU in this case.

The optimizer choice significantly affected learning behavior. While the Adam optimizer consistently led to stable training and lower errors, switching to stochastic gradient descent (SGD) caused the model to completely fail, with training loss quickly becoming undefined (NaN). RMSProp showed better stability than SGD but still underperformed compared to Adam.

Shortening the number of training epochs from 100 to 50 slightly degraded model performance and slowed convergence. This result implies that longer training allows the network to better capture complex relationships in the data, provided that overfitting is properly controlled (e.g., via early stopping).

Finally, changing the batch size from 128 to 64 slightly increased the training error but improved validation performance and convergence speed, suggesting that smaller batches can enhance generalization through the stochasticity introduced into the optimization process.

In conclusion, the experiments confirmed that tuning neural network parameters has a measurable effect on both training efficiency and predictive quality. The findings underscore the importance of a deliberate and data-driven approach to neural network design, especially in technical applications like antenna modeling, where precision is paramount.

V. Future Work

Future research will primarily focus on addressing the inverse problem related to predicting the geometric and material parameters of a patch antenna from a specified resonant frequency. This task is inherently more challenging than forward modeling, as it is ill-posed and may admit multiple feasible solutions, making regularization and prior knowledge essential. Neural network architectures capable of handling such ambiguity, including encoder-decoder frameworks, variational approaches, or physics-informed neural networks (PINNs), will be investigated. In addition, incorporating data from full-wave electromagnetic solvers (e.g., CST, Ansys HFSS) and measured prototypes will allow the models to generalize beyond idealized closed-form equations. Transfer learning strategies may be used to adapt models trained on synthetic data to experimental conditions. Finally, extending the framework towards antenna array synthesis and optimization would demonstrate the broader applicability of the approach in practical microwave engineering.

Another promising direction is the exploration of convolutional or transformer-based models for handling spatial field distributions and antenna arrays. Such architectures may enable direct learning from electromagnetic field maps rather than only scalar parameters, broadening the applicability of the proposed framework

***Abstract*—This work addresses the problem of automatic license plate recognition using computer vision and machine learning methods. An analysis of existing approaches to Ukrainian's license plate recognition was conducted, an optimal neural network architecture was selected, and a software solution was implemented. The proposed system employs modern deep learning algorithms based on YOLOv8 for license plate detection in images and subsequent processing. Image preprocessing, license plate segmentation, and optical character recognition of characters have been implemented. The model was trained using a dataset containing real vehicle images. The proposed solution can be applied in automated parking control systems, road safety enforcement, and law enforcement agencies.**

Keywords—automatic license plate recognition (ALPR), machine learning, neural networks, deep learning, YOLOv8, computer vision, optical character recognition (OCR)

I. Introduction

Automatic license plate recognition (ALPR) is a crucial technology in modern intelligent transportation systems, used for traffic management, law enforcement, and automated parking control. The ability to accurately and efficiently recognize license plates from images is essential for ensuring security and enhancing automation in various domains [1].

The global automatic number plate recognition system market size is calculated at USD 3.79 billion in 2024 and is predicted to reach around USD 9.27 billion by 2034 (Fig. 1) [2].

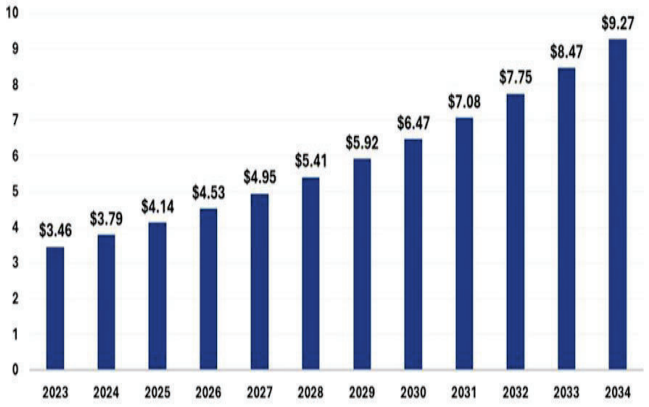

Fig. 1. Automatic Number Plate Recognition System Market Size 2024 to 2034 (USD Billion)

The objective of this work is to develop a robust and efficient license plate recognition system using computer vision and deep learning techniques. The proposed approach involves detecting license plates in images, preprocessing them, segmenting characters, and applying Optical Character Recognition (OCR) for text extraction [3, 4].

This study employs deep learning-based object detection models and OCR algorithms to achieve high recognition accuracy. The dataset consists of real-world images of vehicles with license plates, enabling the model to generalize well to different conditions.

II. Characterization of the License Plate Recognition Problem and Solution Methods

A. Issues and Challenges

Automatic License Plate Recognition is a crucial technology widely used in security, transportation, and parking automation [5]. It enables the automatic identification of vehicles based on their license plates, utilizing advanced computer vision techniques and deep learning models. ALPR plays a significant role in traffic management, law enforcement, and intelligent transportation systems by providing accurate and efficient vehicle recognition in real-time [6].

The main challenges in license plate recognition include:

- Varied fonts and styles of license plates across different countries.
- Impact of weather conditions and lighting on image quality.
- Partial occlusion of the license plate by other objects.
- Partial occlusion of the license plate by other objects.

B. General Characteristics of Ukrainian License Plates

There are many types of different car license plates in Ukraine. They are all defined in the State Standard of DSTU 4278: 2019 [7]. The license plate is the car ID and the person who owns this car. The car license plate of any type has the appropriate characteristics and designated areas. The most common type of license plates – type 1 (Fig. 2), it has the following characteristics: height – 112 mm; length – 520 mm; number of digits – 4; number of letters – 4; the color of the

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

signs – white. The color of the numbers, letters and the ribs of the rigidity of the signs – black.

Fig. 2. The Ukrainian car license plate of type 1

The first two letters in the car license plate indicate the administrative and territorial affiliation of the registration of vehicles in Ukraine (Fig. 3).

Fig. 3. Compounds of letters and numbers denoting the administrative-territorial affiliation of the license plates of vehicles on the map of Ukraine

C. *License Plate Recognition Methods*

Modern ALPR methods are based on the following approaches:

- Traditional computer vision methods: edge detection, character segmentation, threshold binarization methods, and MORPH operations [8, 9].
- Deep learning models: the use of convolutional neural networks (CNN), recurrent neural networks (RNN), and transformers for image processing [10, 11].
- Optical Character Recognition (OCR): Tesseract OCR and neural networks for extracting text from license plates [12, 13].
- Object Detection Models (YOLOv8): YOLO (You Only Look Once) is a state-of-the-art object detection model that provides real-time performance with high accuracy. The latest version, YOLOv8, improves upon previous versions by incorporating advanced features like anchor-free detection, adaptive computation, and transformer-based attention mechanisms [14, 15].

D. *YOLOv8 in License Plate Recognition*

YOLOv8 is particularly well-suited for automatic license plate recognition (ALPR) due to its high detection accuracy, real-time performance, and adaptability to different conditions. The model follows a two-stage pipeline, combining object detection and optical character recognition (OCR).

Logical Structure of YOLOv8 for ALPR.

YOLOv8 operates in two main stages:

- License Plate Detection – the model is trained to detect the bounding box of a license plate in an image. Thanks to its efficient one-stage detection pipeline, it can process multiple frames per second, making it ideal for real-time applications.
- Character Recognition Integration – after detecting the license plate, the extracted region is processed by an OCR model (such as Tesseract OCR or a CNN-based classifier) to recognize the individual characters.

In the YOLOv8 architecture the backbone, neck, and head of the network, which work together to optimize object detection speed and precision [16].

Advantages of YOLOv8 for ALPR:

- Fast and accurate detection, even in real-time applications.
- Robust performance under varying lighting conditions, angles, and occlusions.
- Optimized architecture that balances speed and precision, making it suitable for deployment on edge devices like surveillance cameras.
- Support for transfer learning, allowing fine-tuning on domain-specific ALPR datasets for improved accuracy.

With its efficient structure and real-time capabilities, YOLOv8 provides a reliable solution for automatic license plate recognition, making it highly applicable in traffic surveillance, parking management, and intelligent transportation systems.

III. Result and Discussion

In this project, methods for automatic license plate recognition were examined and implemented using computer vision and deep learning. Specifically, the study focused on the application of convolutional neural networks (CNN), YOLOv8, and optical character recognition (OCR) to develop a high-accuracy license plate recognition algorithm.

The algorithms were implemented using Python 3.9 in the Google Colab development environment, utilizing libraries such as OpenCV, NumPy, Sklearn, and Tesseract OCR. The model execution was carried out in Google Colab with a GP T4 GPU, ensuring high performance and the ability to process large volumes of data in real-time.

The accuracy evaluation of the algorithm was conducted using the following metrics [17]:

- Accuracy – the ratio of correctly recognized license plates to the total number of samples.
- Precision – the proportion of correctly recognized license plates among all detected ones.
- Recall – the proportion of correctly detected license plates among all existing plates in the images.
- F1-score – the harmonic means between precision and recall.
- mAP@0.5 – the mean average precision of an object detection model when the Intersection over Union (IoU) threshold is set to 0.5. In ALPR, mAP@0.5 assesses how well the model detects license plates by evaluating the overlap between predicted and actual plate locations [18].

A. *Data Preparation*

A set of data "License Plate Recognition" using dates from ROBOFLOW [19] and AUTO.RIA [20] websites and

containing 10,000 images of license plates of vehicles that was used for training and testing algorithms was formed to perform the study.

This dataset is structured into three subsets:

- Training set – used to train the model.
- Validation set – used for hyperparameter tuning and evaluating the model's generalization ability.
- Test set – used for the final assessment of model accuracy on unseen data.

The data was split in a ratio of 80% (train) / 10% (validation) / 10% (test).

B. Model Training

To recognize license plates, the YOLOv8 model was trained on the "License Plate Recognition" dataset containing 8,000 images. Training was conducted in Google Colab using a GP T4 GPU over 30 epochs.

Training Process:

- Data Preprocessing – image normalization, augmentation (brightness adjustment, contrast enhancement, rotation).
- YOLOv8 Training – optimization of bounding boxes for precise license plate localization.
- Performance Evaluation – analysis of loss functions, precision, recall, F1-score and mAP.
- Testing on New Images – verifying the model's accuracy in real-world conditions.

Training Results:

- Loss functions (box_loss, cls_loss, dfl_loss) decreased steadily, indicating effective learning.
- Precision: 1.00, Recall: 0.97, F1-score: 0.96, demonstrating high accuracy.
- mAP@0.5 = 97.5%, meaning the model successfully detects license plates in most cases.
- The Precision-Recall curve confirms minimal false detections.

Yolov8 Precision-Recall Curve is presented in Fig. 5.

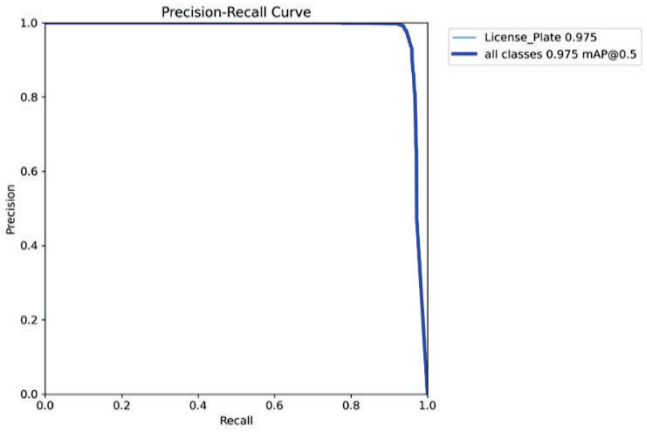

Fig. 5. YOLOv8 Precision-Recall Curve

Yolov8 F1-Confidence Curve are presented in Fig. 6.

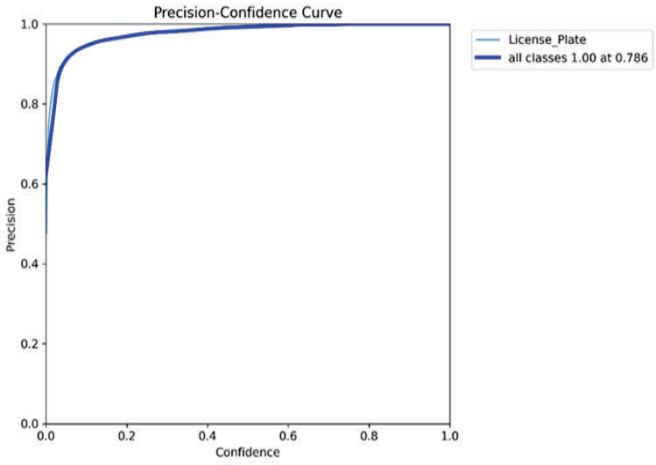

Fig. 6. YOLOv8 F1-Confidence Curve

Yolov8 Training Graphs are presented in Fig. 7.

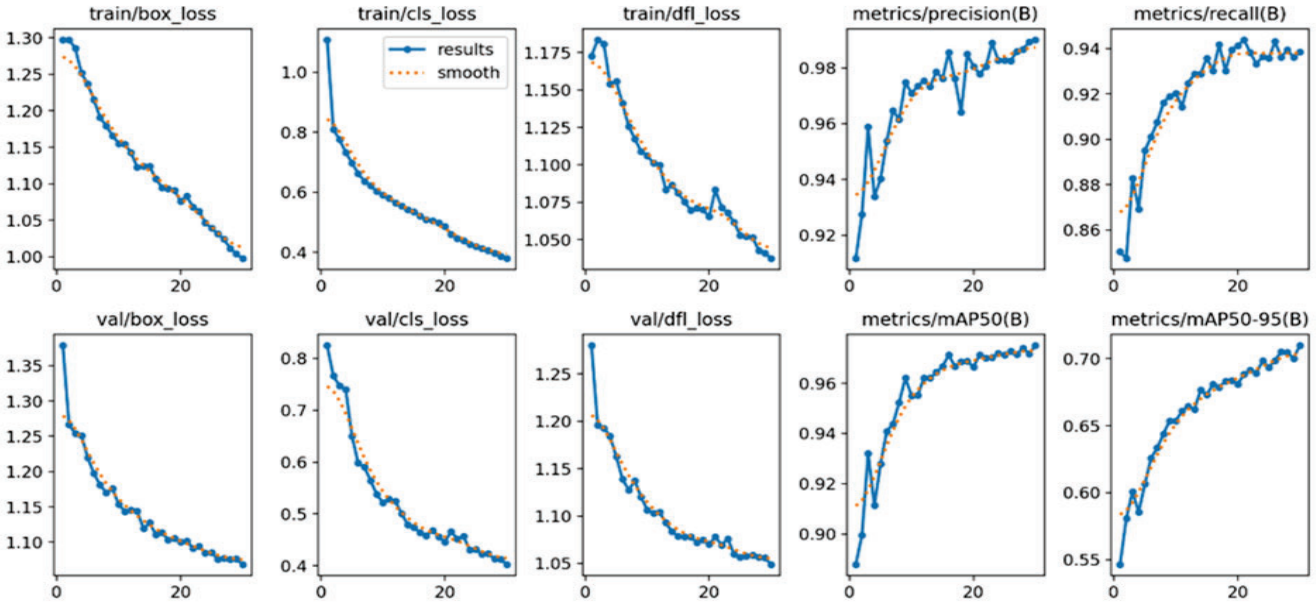

Fig. 7. YOLOv8 Training Graphs (Loss Reduction, Increasing Precision and Recall)

Training Image Examples are presented in Fig. 8.

Fig. 8. Training Image Examples (Batch 0)

The results of training the YOLOv8 model demonstrate its high efficiency in detecting license plates under various conditions. The model successfully achieved 97.5% accuracy (mAP@0.5), confirming its ability to precisely locate and identify license plates in images.

To ensure the robustness of the YOLOv8 model, both validation and test datasets were used for additional evaluation. The performance metrics, including precision and confidence scores, were computed for all datasets. The results are summarized in Table 1.

TABLE I. PERFORMANCE METRICS OF YOLOV8 ON TRAINING, VALIDATION, AND TEST SETS

Dataset	Precision	Recall	F1-score	mAP@0.5
Training	1,00	0,978	0,967	0,975
Validation	0,98	0,97	0,962	0,97
Test	0,975	0,968	0,958	0,96

C. *License Plate Recognition Algorithm*

The license plate recognition algorithm consists of two main stages:

- License plate detection – using YOLOv8 to locate the license plate in the image.
- Character recognition – applying OCR (Tesseract or CRNN) to extract text from the detected plate.

The general workflow of the license plate recognition algorithm is illustrated in Fig. 9.

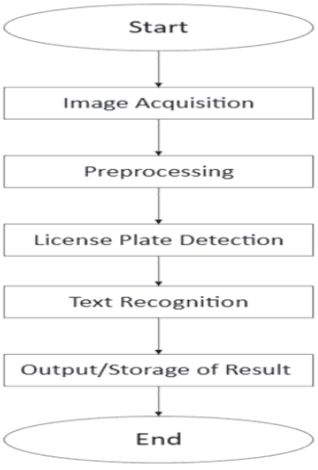

Fig. 1. Flowchart representing the license plate recognition process

Algorithm Steps

1) Image Acquisition

a) The system receives an input image or video frame.

b) The image is resized to 640×640 px for uniform processing.

2) Preprocessing

a) Noise reduction (Gaussian blur, median filtering).

b) Contrast normalization to enhance visibility.

3) License Plate Detection (YOLOv8)

a) Identifies the bounding box of the license plate.

b) Selects the region with the highest confidence score.

c) Extracts the detected plate area for further processing.

4) Text Recognition (OCR)

a) Applies Tesseract OCR or CRNN to recognize characters.

b) Post-processing:

- Removes unnecessary symbols.
- Formats text to match license plate standards (AA 1234 BB).
- Corrects OCR errors (O → 0, I → 1).

5) Output & Integration

a) Displays or stores the recognized license plate in a database.

b) Can be integrated into parking systems, traffic monitoring, and vehicle identification applications.

IV. Conclusions

This study explored and implemented an automatic license plate recognition algorithm based on deep learning. YOLOv8 was used for license plate detection, while OCR (Tesseract/CRNN) was applied for character recognition. The YOLOv8 model achieved high accuracy (mAP@0.5 = 97.5%) in detecting license plates, confirming its efficiency. The optical character recognition (OCR) system ensures correct text extraction, with additional post-processing to correct potential recognition errors. Preprocessing techniques, including contrast normalization and noise filtering, significantly improved detection and recognition quality.

Despite its high accuracy, the algorithm presents some challenges. Blurred, damaged, or non-standard license plates may cause OCR errors, while difficult lighting conditions and partial obstructions can affect detection. Future improvements could include expanding the dataset with real-world images to enhance robustness and optimizing the OCR model by leveraging deep learning-based networks to improve character recognition accuracy. The proposed algorithm can be effectively applied in traffic monitoring systems, automated parking solutions, and violation detection, ensuring reliable and efficient license plate recognition.

***Abstract* — An approach to robot optimal trajectory planning is developed in the study. The robot's environment is filled with multiple obstacles, which must be avoided during the robot's movement. The trajectory length was minimized, and a penalty function was developed to satisfy obstacle avoidance. The trajectory planner is an artificial neural network (ANN) fed with discrete time and generates discrete positions in the Cartesian coordinate system. Comparison with the DC-programming optimization method evidenced the superiority of the developed approach in terms of solution stability. The only revealed drawback of the ANN application is connected with the local optimality of the generated trajectory.**

Keywords — robot, trajectory planning, constrained optimization, nonlinear objective function, VCT-PSO algorithm.

I. Introduction

Trajectory planning is a crucial aspect of autonomous robotics, enabling mobile and manipulator robots to navigate complex environments while avoiding obstacles. Many algorithms have been developed to address this problem, each offering trade-offs between optimality and computational efficiency. Classical graph-based methods such as the A* algorithm [1] provide optimal paths on discretized representations of the environment, serving as a baseline for many state-of-the-art planning strategies. Other commonly used methods – Rapidly-exploring Random Trees (RRT) [2] and its optimal variant RRT* [3] – exploit a sampling-based approach with a probabilistic nature of trajectory search. However, RRT* may suffer from slow convergence in cluttered environments. Covariant Hamiltonian Optimization for Motion Planning (CHOMP) [4] uses functional gradients, allowing it to find smooth, collision-free trajectories. Another optimal method, TrajOpt [5], utilizes sequential convex optimization to generate locally optimal trajectories, combining obstacle avoidance and dynamical constraints. Metaheuristic optimization methods are also widely applied to optimize trajectories [6]. Obstacles in this work are presented as balls, simplifying trajectory design. The application of ANN to develop a robot trajectory [7]. This scientific work stresses the number of ANN inputs and outputs (regarding the signal nature) and the ANN architecture.

In the current study, we proposed an approach that reduces the trajectory planning problem to the ANN training problem. A metaheuristic method was applied to find the solution to the reduced problem.

II. Problem Statement

In order to state the problem in the mathematical sense, one should observe Fig. 1, where the robot environment is presented. It includes the robot position's initial (x_0, y_0) and the final (x_T, y_T) points. The robot is a point mass that obeys the physics laws (for instance, it cannot be in two different points simultaneously, or Newton's laws govern its acceleration and deceleration).

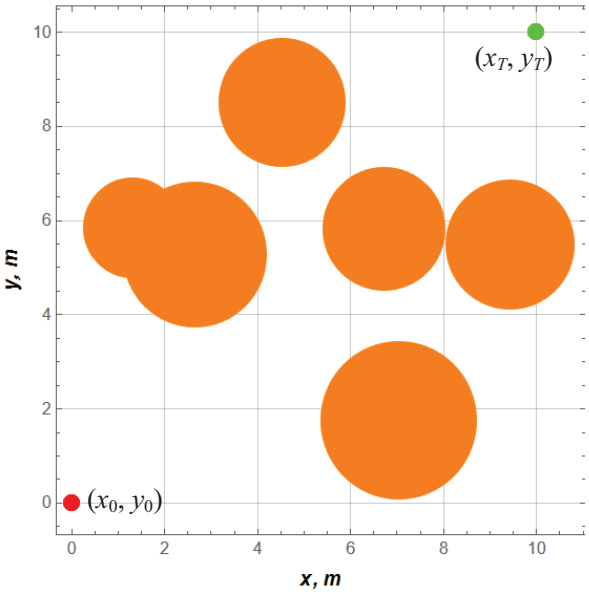

Fig. 1. Robot environment with the denotation of initial (red) and final (green) points and obstacles to avoid (orange discs)

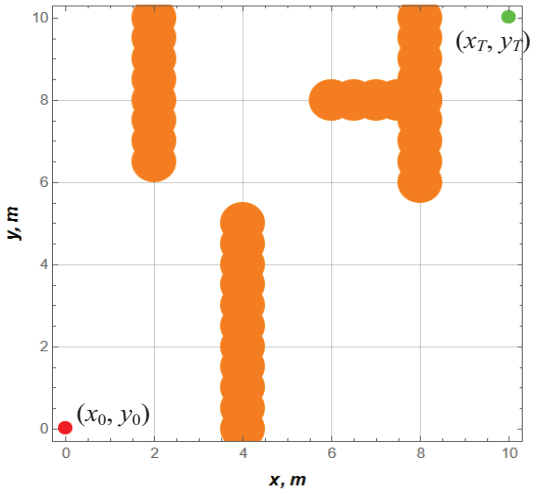
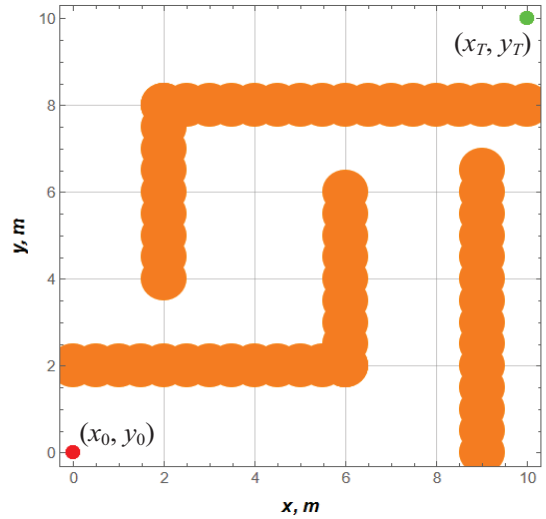
The presented environment (Fig. 1) is a model of the robot's domain – the set of all possible robot positions. The goal of the problem is to find the optimal, in some sense, trajectory (curve) that connects the initial and final points and does not belong to any of the obstacles:



979-8-3503-8909-8/25/$31.00 ©2025 IEEE

$$\begin{cases} \begin{cases} x(0)=x_0;\ \ y(0)=y_0; \\ x(T)=x_T;\ \ y(T)=y_T; \end{cases} \\ x=x(t),\ \ t\in[0,\ \ T]; \\ y=y(t); \\ y=y(x)\notin O_i\ \ \forall i\in[1,\ \ I] \\ \int\limits_{x_0}^{x_T}\left(1+\left(\frac{\partial y}{\partial x}\right)^2\right)dx\to\min; \end{cases} \tag{1}$$



where T – the final time, when the robot reaches the final position; $x(t)$ and $y(t)$ – laws of robot motion along the x and y axes of the „x-y" plane as functions of time; $y(x)$ – law of robot motion as a function of x coordinate; O_i – i-th obstacle; I – total number of obstacles. In many cases, the criterion to minimize is the trajectory length. It is expressed in the last line of the system (1). However, the development of the study approach is not limited to that kind of criterion. Other criteria are possible, and their rational setting and exploitation are issues for further investigations. In the frame of the current study, we assumed that all the obstacles may be presented as discs, with three parameters – two coordinates of a center and a radius. Thus, all the obstacles may be described with the following matrix O_{Ix3}:

$$\mathrm{O}=\begin{bmatrix} x_{o.1} & y_{o.1} & r_{o.1} \\ \dots & \dots & \dots \\ x_{o.i} & y_{o.i} & r_{o.i} \\ \dots & \dots & \dots \\ x_{o.I} & y_{o.I} & r_{o.I} \end{bmatrix}, \tag{2}$$

where O – the obstacle-matrix; $x_{o.\,i}$ and $y_{o.i}$ – the coordinates of the i-th obstacle center; $r_{o.i}$ – the radius of the i-th obstacle. Note that all possible configurations of obstacles may be presented with proper arrangement of disc centres and setting the correct values of discs' radii if $I\to\infty$. In practical cases, I must be big enough. For example, in Fig. 2, two variants of such an arrangement are presented.

a)

b)

Fig. 2. Robot environment with obstacles, which form corridors between initial and final points: a) I=33; b) I=62

Making the value I bigger extends the ability to approximate real obstacles in the robot's environment.

III. Problem Solution

A. Problem reducing

Since the problem (1)-(2) is stated, we should develop an approach to solve it. In the study, we create a strategy involving an ANN approximating the optimal robot trajectory. First, we should note that the solution will search in the discrete form. Thus, continuous functions $x(t)$ and $y(t)$ are replaced by the discrete ones:

$$\begin{aligned} &x(t)\to x_n,\ \ n\in\overline{[1,\ N]}; \\ &y(t)\to y_n. \end{aligned} \tag{3}$$

where N is the total number of discrete time steps.

Next, we must develop the penalty function, which forbids the inclusion of discrete trajectory points into the obstacles O:

$$\begin{aligned} &P=\sum_{n=1}^{N}\sum_{i=1}^{I}P_{i.n.}; \\ &P_{i.n.}=\begin{cases} 0,\ \ if\ \ (x_n,\ y_n)\notin O_i; \\ \delta\left(r_{0.i}-\left\|(x_n,\ y_n)-(x_{0.i},\ y_{0.i})\right\|_2\right), \\ if\ \ (x_n,\ y_n)\in O_i. \end{cases} \end{aligned} \tag{3}$$

where δ – is the weight coefficient (δ=10^6).

Note: to calculate penalty functions, one must check whether every discrete trajectory point belongs to any O_i. To implement this, a loop within a loop must be performed. The inner loop checks whether all the discrete points belong only

to the *i*-th obstacle, and the outer loop does this for all the obstacles.

Let us explain the central concept of penalty function *P* (3). For this, we consider the *i*-th obstacle and the *n*-th trajectory point. Assume that this point belongs to the *i*-th obstacle. Thus, the $P_{i.n}$ is proportional to the Euclidean distance from the point to the *i*-th obstacle boundary (Fig. 3) [5].

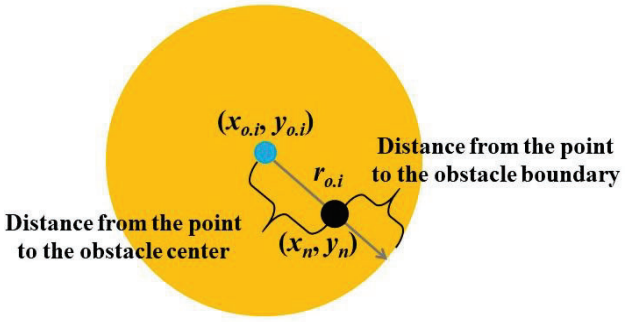


Fig. 3. Graphical explanation of the calculation of the distance from the point to the obstacle boundary

The definite integral (1) for the discrete case must be substituted with the Riemann sum:

$$l = \sum_{n=1}^{N-1} \left\| (x_n,\, y_n) - (x_{n+1},\, y_{n+1}) \right\|_2. \tag{4}$$

Thus, we may write the objective function to minimize:

$$Cr = l + P. \tag{5}$$

B. Selection of the trajectory planner

In order to minimize *Cr,* we must select the proper planner. Since strong approximation properties feature ANN [8] (its ability to map an input to the needed output), we applied it in the study. We consider a one-hidden-layer feedforward ANN with five neurons in the hidden layer.

The parameters of the ANN are given in Table I.

TABLE I. PARAMETERS OF THE APPLIED ANN

Parameter or feature	Value or denotation
Activation function	Arctg
Number of weights	15
Number of biases	7
Domain of weights and biases	-3…3
Domain of gains k_1 and k_2	0…10

The ANN is fed with discrete time $\tau = T/n$ and generates outputs A_1 and A_2, which are post-processed to the discrete functions x_n and y_n (Fig. 4).

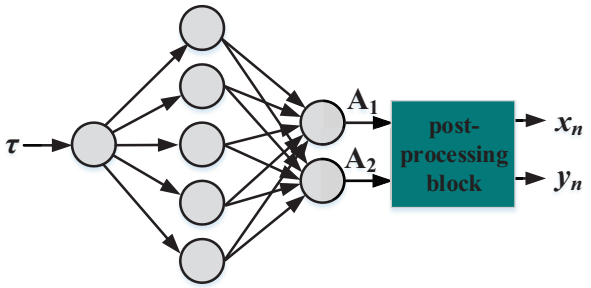

Fig. 4. Graphical representation of the developed ANN

We consider a post-processing block to normalize and gain the ANN outputs A_1 and A_2. It generates dynamically varied values of discrete functions x_n and y_n:

$$\begin{aligned} x_n &= x(0) + \tau\big(x(T) - x(0)\big)\Big(1 + (T-\tau)\pi^{-1} k_1 \mathrm{A}_1(\mathrm{W}, \mathrm{B}, \tau)\Big), \\ y_n &= y(0) + \tau\big(y(T) - y(0)\big)\Big(1 + (T-\tau)\pi^{-1} k_2 \mathrm{A}_2(\mathrm{W}, \mathrm{B}, \tau)\Big), \end{aligned} \tag{7}$$

where k_1 and k_2 – gains of the block; A_1 and A_2 – the first and the second ANNs outputs respectively. To satisfy the boundary conditions of the robot's position (1), the ANN outputs are multiplied by the coefficient $\tau(T - \tau)$. Thus, we may write the reduced problem – the problem of ANN training with reinforcement procedure:

$$Cr(\mathrm{W}, \mathrm{B}, k_1, k_2) \to \min, \tag{7}$$

where W, B – tensor of weights and matrix of biases of ANN, respectively. Indeed, the problem refers to the class of reinforcement learning paradigms. The reward in the problem is inverse to the function (7): the smaller the function (7), the better the ANN is trained.

C. Problem solution with VCT-PSO algorithm

Minimization of the objective function (7) is an unconstrained optimization problem. We may expect a diverse and complicated topology of the function *Cr*. For its minimization, a proper optimizer should be chosen. In the current study, we applied the VCT-PSO algorithm [9] with the following parameters: number of iterations 50, swarm population 30, coefficients $c_1 = c_2 = 1.19$, $w = 0.72$, $RC = 5$. *Cr* reducing during VCT-PSO execution is presented in Fig. 5.

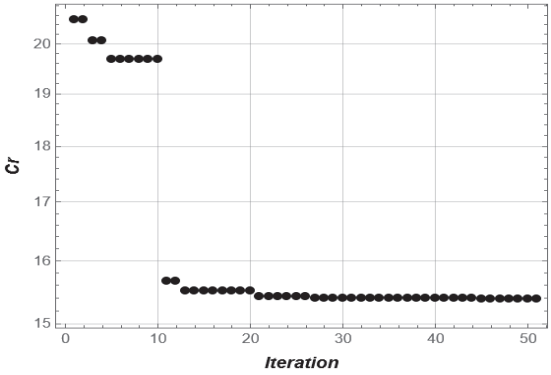

Fig. 5. Objective function reduction during VCT-PSO execution

Fig. 5 evidences that minimization of *Cr* occurred without penalty components: on the first iteration, the VCT-PSO algorithm found a solution without violating the obstacles' boundaries. The algorithm converges quickly at early iterations and slows the convergence rate after the 10th iteration.

IV. Brief Analysis of the Obtained Trajectories

The configuration of the robot's environment with six obstacles and two trajectories is presented in Fig. 6.

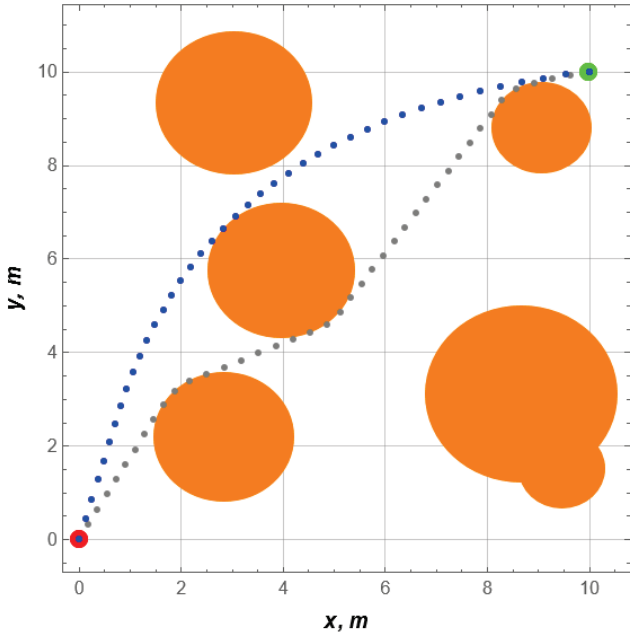

Fig. 6. Two trajectories in the robot's environment with six obstacles

The first trajectory, which is obtained with the described approach, is shown by the blue dots; the second one involves direct numerical calculation of each point's coordinates (the grey dots show it). Since we set N=40, the second solution includes 80 numbers – two coordinates of each point. They were calculated using the DC-programming method [10].

The length of the ANN-based trajectory is 15.34 m, and the second solution trajectory length is 14.75 m.

Fig. 6 shows that the second solution corresponds to the global minimum of criterion (4), while the ANN-based trajectory reaches only the local minimum. However, the features of the ANN-based approach may be revealed with more complicated problems (Fig. 7), i.e., when more obstacles are involved. For the case illustrated in Fig. 7, the VCT-PSO method brings a trajectory length of 17.25 m, and the DC-programming method brings a trajectory length of 29.43 m, which is not even rational. In addition, as one may observe from Fig. 8, both DC-programming trajectories intersect the obstacles, i.e., the constraints of the problem (1) are violated.

Repeated runs of the DC-programming method do not bring better results. Each repeated run of the VCT-PSO method for ANN training corresponds to approximately the same results.

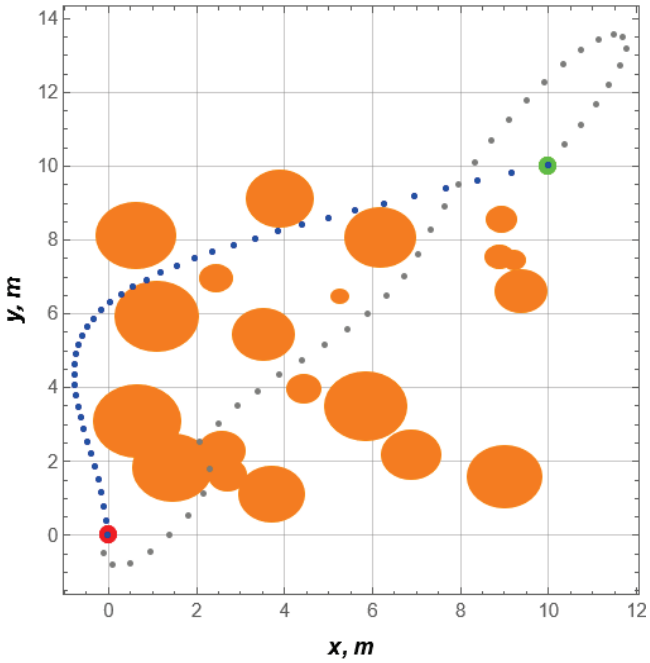

Fig. 7. Two trajectories in the robot's environment with twenty obstacles

Testing both methods for another configuration of the robot's environment (Fig. 8) corresponds to the close results: the DC-programming method fails, the ANN-based approach with the VCT-PSO optimizer allowed to find the local minimum of the trajectory length.

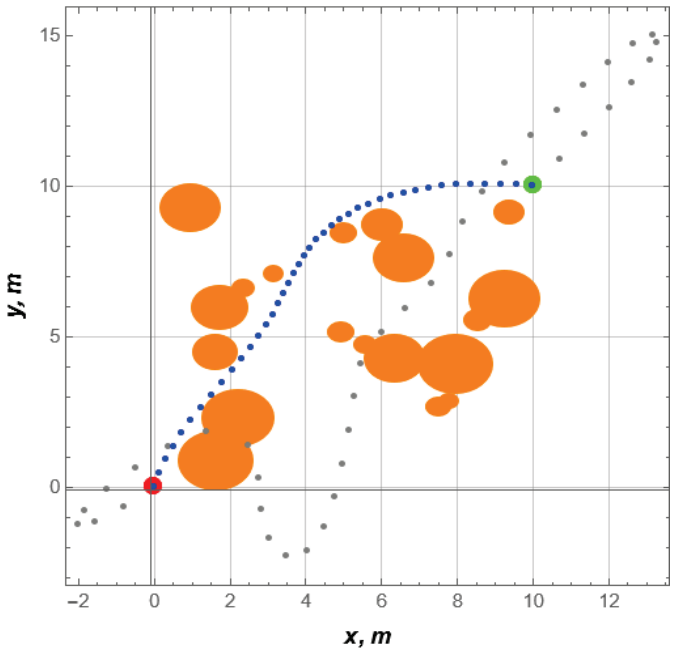

Fig. 8. Two trajectories in the robot's different configuration environment with twenty obstacles

Generally, the ANN-based approach with VCT-PSO optimizer has strong stability of results even for a larger number of obstacles.

To illustrate this statement, we present an ANN-based trajectory in the robot environment with fifty obstacles I=50 (Fig. 9).

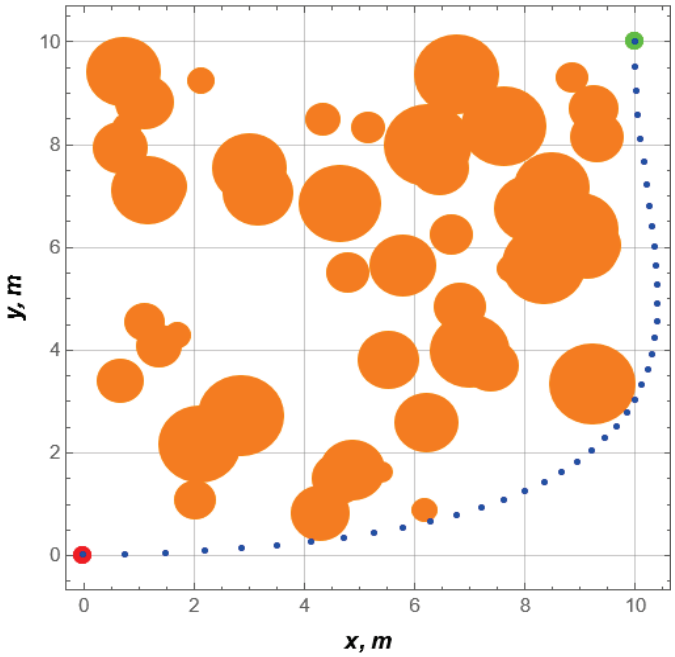

Fig. 9. ANN-based trajectory in the robot's configuration environment with fifty obstacles

However, almost all ANN-based trajectories are locally optimal, which is one possible reason why they are connected with the ANN architecture. Indeed, in the study, a simple ANN was exploited. The bigger number of hidden layers (deeper ANN) allows for building more complicated mapping $\tau \rightarrow (x_n, y_n)$. This thesis is an issue for further studies in this direction.

Another improvement of the developed approach is considering the limitations of the robot's environment. We may note that the additional penalty function must be designed for this reason. It will penalize the distance from where the robot left the environment to the closest boundary. The mathematical description of the additional penalty function will be given in the authors' further works.

V. Conclusions

1. In the study, the problem of planning the optimal trajectory movement of robots was stated. The problem was reduced to an unconstrained one with an ANN-based planner. The objective function of the reduced problem includes only 24 arguments, while the initial problem has 80 of them.
2. To find the problem solution, the VCT-PSO metaheuristic method was applied. It converges to a local minimum, which satisfies all the constraints (obstacle avoidance), but does not correspond to the shortest possible trajectory of the robot movement. Comparison of this approach to the DC-programming method indicates its strong stability even for fifty obstacles to avoid.
3. The issues to consider in the further investigation include, but are not limited to the following items:
   a) making ANN's architecture deeper and figuring out how these changes improve the trajectory;
   b) taking into account the problem statement limitations of the robot's environment as well as different optimization criteria (maximum power consumption, energy losses, etc.);
   c) trajectory planning in 3-D spaces is in the area of interest as well;
   d) further investigation of the developed approach and its comparison with commonly-used algorithms (A*, RRT*, TrajOpt, CHOMP, etc.) is needed to reveal its pros and cons.

***Abstract*— The study determined the optimal cell types for the onboard energy storage device of a hybrid diesel train power plant for various storage device usage scenarios. The use of the storage device for energy accumulation during braking and in plug-in mode was considered. It was established that for the energy storage mode, the use of lithium titanate oxide (LTO) cells is rational in terms of mass and size criteria. In plug-in mode, the minimum mass and size parameters are achieved when using lithium iron phosphate (LFP) and lithium nickel manganese cobalt oxide (NMC) cells. The proposed approach can be used when selecting cells for storage devices for various purposes.**

Keywords—diesel multiple unit, rolling stock, plug-in hybrid powertrain, traction system, energy storage

I. Introduction

Hybrid traction systems incorporating energy storage devices in rail rolling stock offer significant environmental and economic benefits through reduced fuel consumption and emissions [1]. This is confirmed by both theoretical studies and the results of regular operation of rolling stock. The hybridization of Régiolis trains manufactured by Alstom involved replacing several diesel engines with energy storage devices [2] that provided an energy recovery factor of more than 90%, resulting in a 20% saving of resources. The results of the operation of the Ki-Ha E200 railbus equipped with an energy storage device showed a 10% fuel saving [3]. The use of a hybrid powertrain on the HD300 locomotive has reduced fuel consumption by up to 36%, NO_X emissions by up to 62%, and noise by 22 dB compared to the DE10 diesel locomotive, based on which the hybrid locomotive was created [4]. Theoretical researches include the study of the use of hybrid traction systems on mainline locomotives [5, 6], shunting locomotives [7], multiple unit rolling stock [8], and specialized rolling stock [9-11]. The results obtained show fuel savings and a reduction in harmful emissions.

A particularly advantageous application of hybrid systems is in multiple unit rolling stock, where frequent stops allow substantial energy recovery through regenerative braking. Results of the article [12] show that for the domestic diesel train DEL-02, equipped with hybrid power transmission, it is possible to achieve 25% fuel savings. In the article [13], the use of an energy storage device in the traction system of the DMU DEL-02 is considered. In the case of using a plug-in storage device, which is charged from a stationary energy source, a reduction in the cost of fuel and energy resources by 36.5-40.4% is achieved. Thus, the use of energy storage devices contributes to the reduction of operating costs.

For the effective use of storage devices, their technical characteristics must ensure their capability to work in different operating modes. The aim of this study is to determine the rational types of elements for the on-board energy storage device, which is part of the hybrid power unit of DMU, for various options for using the on-board energy storage device.

II. Materials and Methods

Current energy storage technologies in rail applications predominantly utilize lithium-based cells [14, 15]. There are applications and theoretical studies on using supercapacitors [12, 16], inertial storage devices [17], and sodium-sulfur cells [18]. Also, lead batteries of different types are used on various rolling stock [19]. The characteristics of the cells vary, and therefore the task of determining the best type of cells for a specific application arises.

In the article [13], the use of energy storage devices as part of the traction system of the DEL-02 DMU is researched. Three options for using the storage device are considered:

1) the storage device accumulates energy during electrodynamic braking and uses it during acceleration (first option);
2) the storage device provides power during movement except for acceleration and accumulates energy during electrodynamic braking (second option);
3) the energy storage device is used instead of one diesel generator set (third option).

In all three cases mentioned above, electrodynamic braking is performed by all traction electric motors.

Table 1 shows the parameters of the energy storage devices. In this case, for the first and second options, it is necessary to use two storage devices since the serial DMU DEL-02 is equipped with two diesel generator sets. In the third option, one storage device is required, which is installed instead of one diesel generator set. The operation of the traction asynchronous electric drive of the DMU is not studied in this work. However, it is worth noting that to increase energy efficiency indicators, an adaptation of the traction electric drive to work with a hybrid power unit is necessary [20-22].

Minimal dimensions and weight are important for onboard energy storage devices. This stems from the fact that there are restrictions on the maximum load on the rails from the vehicle and the dimensions of the rolling stock. Therefore, it seems appropriate to use the weight and size parameters of the storage device as a criterion for determining its applicability to rolling stock. Since cells account for a significant portion of the mass and volume of the onboard storage device, their mass

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

and the volume required for placement are calculated using the methods described below.

This study focuses on the use of supercapacitors and lithium cells in the storage. Consideration of inertial storage requires a separate study of the storage itself, which is beyond the scope of this study.

Table 2 shows the parameters of some elements of certain types, which are selected for calculations. Lithium cells were selected in such a way as to reflect different characteristics depending on the chemical structure. The data in Table 2 is used in calculations according to the methods described below. In all calculations, it is assumed that the cell current corresponds to the C-rate value.

TABLE I. ENERGY STORAGE PARAMETERS [13]

Type	Energy storage power rating, kW	Operating capacity, kW·h
1	468	28.7
2	468	200
3	835	450

Mass, kg	0.475	0.515	1.4	1.62	0.855

The calculation of the number and parameters of the supercapacitor storage device was made following [28].

The number of supercapacitors required to form a storage device of a given operating energy capacity:

$$N_{sc1} = (2E) / (U^2_{sc}\, C_{sc}\, (1\text{-}d^2)) \quad (1)$$

where E – operating energy capacity,

U_{sc} – supercapacitor rated voltage,

C_{sc} – supercapacitor capacity,

$d = U_{min} / U_{sc}$ – supercapacitor discharge depth,

U_{min} – minimum voltage on a supercapacitor.

Number of supercapacitors required to provide storage capacity:

$$N_{sc2} = P / (U_{sc}\, I_{sc}\, d) \quad (2)$$

where P – storage power rating,

I_{sc} – supercapacitor permissible current.

The values obtained by (1) and (2) are rounded to the nearest higher number. The number of supercapacitors to create an energy storage device of a given energy capacity and power is defined as:

$$N_{sc} = \max (N_{sc1}, N_{sc2}) \quad (3)$$

The number of supercapacitors determined by (3) will satisfy only one of the expressions (1) or (2).

After determining the number of supercapacitors, the value of the working energy capacity is specified:

$$E' = (U^2_{sc}\, (1\text{-}d^2)\, N_{sc}\, C_{sc}) / 2 \quad (4)$$

Specified power rating:

$$P' = N_{sc}\, U_{sc}\, I_{sc}\, C_{sc}\, d \quad (5)$$

Minimum storage voltage:

$$U_{sc\min} \approx U_{dc}\, d \quad (6)$$

where U_{dc} – DC-link voltage.

Cells mass:

$$M = N_{sc}\, m_{sc} \quad (7)$$

where m_{sc} – weight of one supercapacitor.

The volume required to accommodate the cells, excluding the structural elements of the storage device

$$V = abhN_{sc} \quad (8)$$

where a, b, h – the length, width and height of one cell, respectively.

Equations (7) and (8) determine the total mass and volume required to accommodate supercapacitors. Features such as the supercapacitor connection scheme, storage design, etc., which may affect mass and volume, are not taken into account in this study.

The calculation of the quantity and parameters of the lithium-ion battery is performed according to [29].

The capacity of the energy storage device is determined as follows:

$$E_{es} = \Delta E / ((SOC_{max}–SOC_{min})(1–D)k) \quad (9)$$

where ΔE – operating energy capacity,

SOC_{max} – maximum permissible cell charge level,

SOC_{min} – minimum permissible cell charge level,

D – reduction in storage capacity over service life, accepted as equal to 20%.

k – the coefficient that takes into account the decrease in the capacity of the energy storage device due to temperature changes, self-discharge, “overcharging” of the cell, etc. For the estimates made in this study, the coefficient can be taken as 0.9.

SOC_{max} and SOC_{min} values are from the storage cell datasheet.

Number of storage cells provided that the operating energy capacity is ensured

$$N_{li1} = E_{es} / E_{cell} \quad (10)$$

where E_{cell} – the energy that one cell can give off when discharged with current I_{cell}. Typically, the current I_{cell} corresponds to the C-rate indicator recommended by the cell manufacturer.

Number of cells with capacity provision condition:

$$N_{li2} = P / (U_{\min} I_{cell}) \quad (11)$$

where $U_{\min}$ – the cell voltage above which the battery must operate at full capacity. It can be taken to be equal to the cell open circuit voltage at a cell state of charge equal to SOC_{min}. It is determined by the SOC–OCV curve of the cell.

The number of cells is determined by the expression:

$$N_{li} = \max (N_{li1}, N_{li2}) \quad (12)$$

Specified energy storage capacity

$$E'_{es} = N_{li} E_{cell} \quad (13)$$

Specified available energy storage capacity:

$$P'' = N_{li} U_{\min} I_{cell} \quad (14)$$

Minimum voltage of the energy storage device

$$U_{li\min} \approx (U_{dc} / U_{\max}) U_{\min} \quad (15)$$

where $U_{\max}$ – the maximum cell voltage can be taken equal to the cell open circuit voltage at a cell charge level equal to SOC_{max}.

The mass and volume are calculated by (7) and (8), respectively using the number of lithium cells calculated by (12).

Thus, the above expressions allow us to determine the mass of the cells and the volume required for their placement. These values allow us to determine whether it is possible to use cells of this type in a storage device, as well as to compare the mass and dimensional parameters of storage devices with different cells.

III. Results and discussion

The calculation of the parameters of the storage that uses supercapacitors was performed according to (1)-(8). In the calculations, it was assumed that the depth of discharge of the supercapacitor is 0.3, since the optimal depth of discharge determined according to [28], equal to 0.1, leads to a large voltage regulation range. This negatively affects the mass and dimensions of the matching converter, with the help of which the supercapacitor accumulator is connected to the traction system. It is worth noting that previous calculations showed that the depth of discharge does not affect the number of cells, since in the studied case their number is determined precisely by the operating energy capacity.

The calculation of the parameters of the storage that utilizes lithium cells was performed according to (9)-(15). In this work, mass and dimensions are used to determine the rational option: the smaller the mass of the cells and the overall volume, the more suitable the accumulator is for use on rolling stock. Economic aspects and cell lifecycle resources are not analyzed in this study.

Tables 3-5 show the results of calculating the parameters of energy storage devices for each option with different types of cells.

According to Tables 3-5, the largest volume and mass of cells have storage devices formed from supercapacitors. For the second option, the mass of the storage device is comparable to the mass of the car, and for the third, it exceeds the mass of the car. Therefore, the use of such a storage device is not possible.

When using lithium cells, the parameters of the storage devices depend on the use case. For the first option (Table 3), the largest mass and volume have storage devices with LFP cells Eve LF50K. For other types of lithium cells, the mass and dimensions of the storage device are close. It is worth noting that the capacity of the storage devices is in the range of 194-974 kW·h, which significantly exceeds the required operating capacity. It is unlikely that the use of such a storage device in the first option is appropriate. A possible way to create a storage device with more consistent parameters for the operation of the first option is to use LTO cells with different parameters – lower capacity and higher operating current.

TABLE III. Energy storage parameters for the first option (28,7 kWh, 468 kW)

Parameter	**Value**				
Cell	***Maxwell BCAP3000 P270 K04 [23]***	***Toshiba SCiB 20Ah [24]***	***Eve LF50K [25]***	***CALB L148F88A [26]***	***SVOLT 51Ah [27]***

TABLE V. ENERGY STORAGE PARAMETERS FOR THE THIRD OPTION (450 KWH, 835 KW)

Parameter	**Value**				
Cell	***Maxwell BCAP3000 P270 K04 [23]***	***Toshiba SCiB 20Ah [24]***	***Eve LF50K [25]***	***CALB L148F88A [26]***	***SVOLT 51Ah [27]***
Number of cells	162800	17429	10440	3045	5220
Capacity, kW·h		802	1670	857	852
Rated power, kW		2248	835	857	852
Maximum voltage, V	1500	1503	1501	1501	1501
Minimum voltage, V	500	1285	1384	1366	1381
Occupied volume, m^3	76.2	4.7	7.7	2.4	2.0
Mass, t	77.3	9.0	14.6	4.9	4.5

The calculation results for the second option (Table 4) show that the best mass and dimensional indicators have storage devices with LFP cells CALB L148F88A and NMC cells SVOLT 51Ah. The energy storage device on LTO cells has slightly worse indicators. The storage device with LFP cells Eve LF50K has the highest mass and volume, so based on this criterion, its use is not advisable. From Table 4 it follows that the energy capacity of the storage devices for this option is 360-497 kW·h, which exceeds the operating one. This will allow for longer operation in the case of using an energy storage device according to the second option. To create a storage device with parameters that are closer to the operational according to second option, it is necessary to use cells with other characteristics.

Calculations for the third option (Table 5) are similar to the results obtained for the second one. The best mass and dimensional indicators are provided by storage devices with LFP cells CALB L148F88A and NMC cells SVOLT 51Ah. At the same time, the actual capacity exceeds the required one by approximately two times, which allows for movement without charging the storage device for a longer time.

Thus, the calculations confirm the possibility of creating an energy storage device for the traction system of a DMU. For the first option, it is considered advisable to use a storage device based on LTO cells. As the calculations show, for the second and the third options, storage devices based on LFP and NMC cells are advisable. A possible option is LTO cells with improved mass and dimension indicators of the storage.

It is worth noting that in the second option, the energy storage must be integrated into each of the two diesel generator sets. In the third option, one of the diesel generator sets is replaced by an energy storage. As can be seen from the calculations, the mass and volume of two storage units for the second option exceed the mass and volume of one storage unit for third one. In this case, in the second option, it is necessary to place the storage units and related equipment on the cars. In the third option, the storage unit can be installed in place of the diesel generator set that will be dismantled. To ensure the operation of the storage unit according to the third option, it is necessary to connect the traction systems located on different cars. For the final choice of option, it is necessary to study the placement of equipment and assess economic indicators, in particular, taking into account the need to replace cells due to their degradation [30].

IV. CONCLUSIONS

The use of energy storage devices in the traction system of a diesel train with electric power transmission is considered. The parameters of the energy storage device for different cases of its use are determined. According to the criterion of minimum mass and size indicators for the case of braking energy accumulation, it is rational to use LTO cells. In this case, the mass of the cells is 2.2 tons, and the volume required for placement is 1.1 m^3. When using a plug-in storage device, it is advisable to use LFP and NMC cells in energy storage devices. The minimum weight of LFP cells is 2.8 tons and 4.9 tons, and the minimum weight of NMC cells is 2.6 tons and 4.5 tons. The volume required for cell placement is 1.4 m^3 and 1.2 m^3, respectively. To finally decide on the type of cell, you need to figure out its service life and check out the economic effects of using onboard energy storage in hybrid power units for rail rolling stock.

***Abstract*—The paper presents a study of integral stiffness and damping characteristics of active magnetic structural elements which provide a suspension of the vibration isolation system depending on possible operating conditions and parameters of the internal structure of the electromagnetic and electromechanical parts of the rotating machine. The approach to the investigation of the dynamic coefficients of the vibration isolating supports consists in considering the transfer functions of active magnetic bearing components joined into the interconnected system including the electric and rotating mechanical components. The methodology is applied to the solution of the practical problem of avoiding the resonant state of the industrial fan and electric motor assembly by the proper selection of stiffness and damping characteristics of its supports with varying bias current of the electromagnet of the active magnetic structural suspension element. The investigation will be valuable for engineers and scientists who are engaged in the research and development of active electromagnetic systems.**

Keywords—vibration isolation, active magnetic suspension, dynamic coefficients, electromagnet, electric motor

I. Introduction

At the moment, the nonlinear structural analysis suggests engineers and scientists a rich variety of tools to analyze the problems of different nature, from the complex modelling of the destructive processes in the pretensioned structures [1] to the simulation of the rotor dynamics behavior under the impact of the foreign objects [2]. However, even for these cases, it was shown that the linear approach can be applied with some restrictions, for example, the nonlinear impact of the objects can be simplified to the action of force [3] to model the mechanics of the rotor structure without the significant decrease of the accuracy [4].

This approach is also applicable to modelling of the rotor bearings as linear supports with their own stiffness and damping properties [5] which was effectively used by the authors to model the dynamics of rotors in active magnetic bearings [6], [7].

The benefit of using the magnetic levitation is actively used in transportation and turbomachinery fields [8]. Along with passive magnetic bearings [9], active magnetic bearing (AMB) technology offers significant benefits over a conventional bearing and is increasingly being used in different fields of industry. Using AMBs instead of traditional oil-lubricated or rolling element bearings in turbomachinery results in oil-free operation with reduced maintenance, increased efficiency due to lower power losses, and improved reliability because of the controllable dynamic behavior of the system and absence of wear between a shaft and suspension.

This scientific study was supported and partially funded by National Research Foundation of Ukraine (NRFU grant number 2023.03/0255).

Active magnetic bearings have been reaching high popularity among engineers and scientists as support systems for high-speed and low-friction machines. Since 1980s, applying them became a promising option when designing new turbomachine units or dealing with instability issues in the existing ones [10].

The main idea of the active magnetic bearing operation is based on the electromagnetic processes. It works on the principle of electromagnetic suspension. An electrical current passing through densely wound copper coils creates a magnetic field. This field interacts with a rotor sleeve which is made of a magnetic material such as Silicon-Iron. Levitation of a rotor in AMBs results in a number of their advantages [11] among which are the capability to vary stiffness and damping coefficients providing smooth passing through the resonances.

The size range of machines with AMBs varies from very small to big applications with power and speed limits of 30 MW and 150000 rpm. Active magnetic bearings are used:

- In natural gas extraction and transportation systems for compressors, turboexpanders, and expander-compressor units [12], [13], [14].
- In power industry for steam and gas turbines [15], [16].
- For electrical machines [12].
- For some specific applications where the other types of bearings are inapplicable, such as nuclear centrifuges, energy storage flywheels, machining spindles, turbomolecular pumps, etc. [17], [18], [19], [20].

The approaches to simulation of the dynamics of the 'rotor in AMBs' system as a mechatronic one has its own features in comparison with the standard rotor dynamics (RD) modelling since the interconnectedness of electromagnetic and mechanical systems should be adequately taken into account. Depending on the needs and complexity of the system, these approaches may include:

- Analytical [21] or numerical [22] determination of AMB stiffness and damping parameters with further RD simulations considering the 'rotor in spring-damper supports' models [23].
- Experimental identification of AMB control system parameters [24] with further modelling of its operation in connection to the rotor response including test rig validations [25], [26].
- In-depth modelling of all AMB components [27] with further application of optimization algorithms [28], particularly neural network capabilities [29], to seek

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

for the AMB optimal parameters which provide the 'rotor in AMBs' system with the smoothest passing through the resonances and safe operation on the operational regimes.

Despite the high attention to the innovative technology and advantages that AMBs provide, their use is limited due to the complexity of the process of design, analysis, and integration into a machine. The fact that rotors with AMBs are mechatronic systems means that both mechanical and electromagnetic processes take place in the systems simultaneously. Therefore, the comprehensive modelling of AMB component properties and features is crucial when designing the turnkey turbomachines with active magnetic bearings or constructing the AMB plants for the existing machines to replace the outdated or improperly selected bearings. The more adequate AMB models are, the easier switching from these models to the real structure becomes since it provides engineers with better correspondence between model parameters and real properties of AMB components. This enables the widest possible optimization capabilities with an opportunity to tune each feature of a certain AMB component in order to reach the best vibrational properties of the 'rotor in AMBs' mechatronic system.

The goal of the current work is to show the applicability of the approach for modelling of AMBs by their stiffness and damping properties without a decrease in the simulation accuracy which allows to model the rotor dynamics behavior of the machine properly.

The entire approach allows increasing of the mechatronic system efficiency by the possibility to accurately predict its rotor dynamics response which enables switching to such friction-free supports as AMBs and decreases the losses due to friction in bearings.

The rising popularity of AMBs among engineers and scientists provides this work with high relevance, and its novelty is determined by the unique set of input data of the AMB components, namely amplifier features, electromagnet physical properties, controller tunings, antialiasing filter and sensor parameters available for optimization during RD simulations of the considered mechatronic machine.

II. Theoretical Foundation of the Approach

A. Electromagnetic Part Dynamics

To describe the electromagnetic part dynamics, the frequency domain is used. The relation between the frequency domain s and the time domain t is driven by the Laplace transform which for a random function $f(t)$ defined in the range $t \in [0, +\infty]$ is represented by the following operator [30]:

$$\mathcal{L}\{f(t)\} = \int_0^{+\infty} \mathrm{e}^{-st} f(t)dt. \quad (1)$$

The approach presented in the paper utilizes the proportional-integral-derivative (PID) controller model with single input-single output control (SISO) principles which conditions the correspondence between amplifier voltage u and delay voltage u_{delay}:

$$u(s) = G_{PID}(s)u_{delay}(s). \quad (2)$$

The amplifier is considered as a bandwidth-limited transconductance device which presents the relationship between current i_{mag} and voltage u with a closed-loop transconductance $G_{amp}(s)$:

$$i_{mag} = G_{amp}(s)u. \quad (3)$$

Three other AMB components, namely sensor, antialiasing filter, and delay, are connected in a series:

$$\begin{aligned} u_{delay} &= G_{delay}(s)G_{aa}(s)G_{sense}(s)y_{sense} \\ &= G_{out}(s)y_{sense}, \end{aligned} \quad (4)$$

which introduces the correspondence between displacement y_{sense} measured in the sensor and delay voltage u_{delay}.

Finally, the relationship between the current and the displacement measured in the sensor is:

$$i_{mag} = G_{amp}(s)G_{PID}(s)G_{out}y_{sense} = G(s)y_{sense}. \quad (5)$$

This relationship is further transformed to the bearing dynamic coefficients which is a part of the approach and will be shown in the following subsections.

B. Transfer Functions of AMB Components

Although it is proven that the advanced multiple input-multiple output (MIMO) [31] control algorithms like H_∞ [32], [33] give robust control possibilities [34], [35], experiments show [36], [37] that simple analogue schemes can still be used as one of the variants of AMB assemblies for turbomachines to get the benefits of the rotor behavior control [38].

The following table contains the formulas for transfer functions of the AMB components which model their dynamics based on the experience from the provided papers.

TABLE I. AMB Component Transfer Functions

Component	Transfer Function		
	Formula	***Parameter***	***Value***
Controller	$G_{PID}(s) = \frac{K_D s + K_P}{(\tau_1 s+1)(\tau_2 s+1)} + \frac{K_I}{s}$	K_D [µs]	449.3
		K_P [-]	1.362
		K_I [s^{-1}]	82.6
		τ_1 [µs]	33
		τ_2 [µs]	11
Amplifier	$G_{amp}(s) = \frac{k_{amp}}{\frac{s^2}{4\pi^2 f_{b1}^2} + \frac{2\xi s}{2\pi f_{b1}} + 1}$	k_{amp} [-]	1
		f_{b1} [Hz]	1200
		ξ [-]	0.8
Sensor	$G_{sense}(s) = \frac{\frac{u_{max}-u_{min}}{m_r}}{\frac{s}{2\pi f_{b2}} + 1}$	u_{min} [V]	-25
		u_{max} [V]	25
		m_r [m]	0.001
		f_{b2} [Hz]	8000
Sampling delay model	$G_{delay}(s) \approx \frac{24\tau^2 s^2 + 240}{\tau^3 s^3 + 12\tau^2 s^2 + 60\tau s + 120} - 1$	τ [µs]	100
Antialiasing filter[a]	$G_{aa}(s) = \frac{\frac{\alpha^2}{4\pi^2 f^2} s^2}{\frac{1}{4\pi^2 f^2} s^2 + \frac{2\beta}{2\pi f} s + 1}$	α [-]	0.95
		β [-]	0.05
		f [Hz]	100

[a.] The second-order low-path antialiasing filter is used to condition the sensor signals before they are sampled by the proportional-integral-derivative controller.

The values of the parameters, presented in the table, are used for the further consideration of the case of the rotor in active magnetic bearings.

C. Rotor Dynamics Model

The flexible rotor model for the finite-element formulation is described by the matrix form of equilibrium equations including mass [*M*], damping [*C*], gyroscopic [*D*] and stiffness [*K*] matrices and displacement vector $\{z\}$ in relation to the nodal force vector $\{f\}$ [39]:

$$[M]\{\ddot{z}\} + ([C] + \Omega[D])\{\dot{z}\} + [K]\{z\} = \{f\}. \quad (6)$$

For the case of the unbalance response of the 'rotor in AMBs' system, the nodal force vector can be divided into unbalance $\{f_u\}$ and AMB $\{f_{AMB}\}$ forces:

$$\{f\} = \{f_u\} + \{f_{AMB}\}. \quad (7)$$

The relation between the global AMB force vector $\{f_{AMB}\}$ and local bearing force vector $\{f_a\}$ is described by the "local to global" transformation matrix $[T_A]$:

$$\{f_{AMB}\} = [T_A]^T\{f_a\}. \quad (8)$$

The same matrix also represents the local displacement vector in actuator locations $\{z_a\}$ in terms of the overall displacement vector $\{z\}$:

$$\{z_a\} = [T_A]\{z\}. \quad (9)$$

The local bearing force vector $\{f_a\}$ in general is a nonlinear function of the control currents in the bearings $\{i_a\}$ and of the local displacement vector in actuator locations $\{z_a\}$. Consideration of small deviations around a static equilibrium point allows this function to be simplified to the linearized form:

$$\{f_a\} = k_s\{z_a\} - k_i\{i_a\}. \quad (10)$$

The actuator gain k_i and the actuator nominal stiffness k_s depend on the actuator parameters, including the magnetic permeability of a vacuum $\mu_0 = 4\pi*10^{-7}$ H/m, the number of turns of coils per a horseshoe pair *N*, pole cross-sectional area *A*, the half of the angle between two poles θ, the bias current i_b, and the nominal air gap s_0 [40], [41]:

$$\begin{aligned} k_i &= \frac{\mu_0 N^2 A \cos\theta\, i_b}{s_0^2}; \\ k_s &= -k_i \frac{i_b}{s_0}\cos\theta. \end{aligned} \quad (11)$$

The bias current i_b is determined based on the required target stiffness value k_t of the AMB:

$$i_b = \sqrt{\frac{s_0^3 k_t}{\mu_0 N^2 A \cos\theta(1+\cos\theta)}}. \quad (12)$$

Therefore, the resulting AMB force vector can be rewritten:

$$\{f_{AMB}\} = [T_A]^T(k_s\{z_a\} - k_i\{i_a\}). \quad (13)$$

Neglecting the amplifier dynamics considered in the G_{amp} expression in Table 1 and assuming the collocation of actuators and sensors corresponding to them which means that $\{y_{sense}\} = \{z_a\}$ (the displacement signals in the sensor locations are equal to the displacements in actuator locations) allows considering the equation (5) expressed in the local vector form as:

$$\{i_a\} = [G(s)]\{z_a\}. \quad (14)$$

where $[G(s)]$ is the diagonal matrix in case of the SISO control with the diagonal components equal to the transfer functions from the equation (5) with parameters individual for each direction in each AMB (for two radial AMBs with two controlled directions this is a 4x4 diagonal matrix).

If to assume further that the AMB structure is the same in horizontal and vertical directions and the control system is tuned for the equivalent feedback in horizontal and vertical directions, this will allow considering all the diagonal components in the matrix $[G(s)]$ equal to each other and the expression (14) will be simply written as follows:

$$\{i_a\} = G(s)\{z_a\}. \quad (15)$$

Substituting the equations (7), (13) and (15) into (6) with going from the Laplace transform variable to the excitation frequency variable $s = j\omega$ gives:

$$\begin{aligned} &[M]\{\ddot{z}\} + ([C] + \Omega[D])\{\dot{z}\} + [K]\{z\} \\ &-k_s[T_A]^T[T_A]\{z\} + k_i G(j\omega)[T_A]^T[T_A]\{z\} = \{f_u\}. \end{aligned} \quad (16)$$

Here $j = \sqrt{-1}$ is the imaginary unit. Note that in this equation the only complex term is still $k_i G(j\omega)[T_A]^T[T_A] = \Re\mathrm{e}(k_i G(j\omega)[T_A]^T[T_A]) + j\Im\mathrm{m}(k_i G(j\omega)[T_A]^T[T_A])$. As the unbalance response of the rotor is a type of the harmonic response due to the harmonic force $\{f_u\} = \Re\mathrm{e}(\{F_u\}\mathrm{e}^{j\omega t})$ with the excitation frequency coinciding with the rotational speed, the solution of the equation (16) can be searched in the same form $\{z\} = \Re\mathrm{e}(\{Z\}\mathrm{e}^{j\omega t})$. Substituting these forms into the equation gives the following change:

$$\begin{aligned} &(-\omega^2[M]\{Z\} + j\omega([C] + \Omega[D])\{Z\} + [K]\{Z\} \\ &-k_s[T_A]^T[T_A]\{Z\} + k_i G(j\omega)[T_A]^T[T_A]\{Z\})\mathrm{e}^{j\omega t} \\ &= \{F_u\}\mathrm{e}^{j\omega t}. \end{aligned} \quad (17)$$

Simplifying and rearranging this expression gives:

$$\begin{aligned} &-\omega^2[M]\{Z\} + j\omega([C] + \Omega[D] \\ &+\Im\mathrm{m}(k_i G(j\omega)[T_A]^T[T_A])/\omega)\{Z\} \\ &+([K] - k_s[T_A]^T[T_A] + \\ &+\Re\mathrm{e}(k_i G(j\omega)[T_A]^T[T_A])\{Z\} = \{F_u\}. \end{aligned} \quad (18)$$

The additional multipliers at the second and third terms of the equilibrium equations are the impacts of the active magnetic bearings on the rotor system. As they are additives to the stiffness and damping matrices of the rotor, they can be considered as the stiffness and damping matrices of the active magnetic bearings which are written in the following form:

$$\begin{aligned} [K_{AMB}] &= \left(-k_s + \Re\mathrm{e}(k_i G(j\omega))\right)[T_A]^T[T_A]; \\ [C_{AMB}] &= \Im\mathrm{m}\left(k_i G(j\omega)\right)/\omega)[T_A]^T[T_A]. \end{aligned} \quad (19)$$

In view of the same parameters for each direction of each AMB and the fact that the excitation frequency is equal to the rotational speed Ω for the rotor unbalance response, their stiffness and damping in both directions can be calculated:

$$k_{AMB} = -k_s + k_i * \Re\mathrm{e}\big(G(j\Omega)\big); \\ c_{AMB} = k_i * \Im\mathrm{m}(G(j\Omega))/\Omega. \tag{20}$$

These simple relations are used for the calculation of the rotor critical speeds to represent the rotor in AMBs as in the spring-damper elements with properties which are dependent on the rotational speed.

III. Case Study of the Rotor in AMBs

A. Background of Using the AMBs in the Rotor

The paper [5] considered a rotor of the axial industrial fan shown in Figure 1 to determine its static strength and modal characteristics based on the three-dimensional finite-element approach which allows calculating the mode shapes associated with the vibrations of the blades, the disc, the shaft, etc. However, in this paper, only first six natural frequencies were considered which were not associated with the shaft deflection, and the bearings were modeled as rigid ones since the rotor dynamics natural frequencies were higher than the considered natural frequencies.

The structural analysis did not consider the significant drop in the efficiency of the machine due to the increased frictional losses in the rolling element bearings because it was out of scope of that study. However, due to the underloading of the bearings, the slippage of rolling elements occurred which led to the necessity of using the increased clearance but did not resolve the issues of the rolling element bearing effect on the machine efficiency.

To overcome this issue, it was suggested to use a simple scheme of active magnetic bearing support with SISO PID control which is relatively cheap to implement in comparison with the advanced MIMO digital schemes but should give the desired benefit of reducing the frictional losses in the supports and having a controllability on the rotor resonances which may arise due to the transfer from the rolling element bearings to the active magnetic bearings.

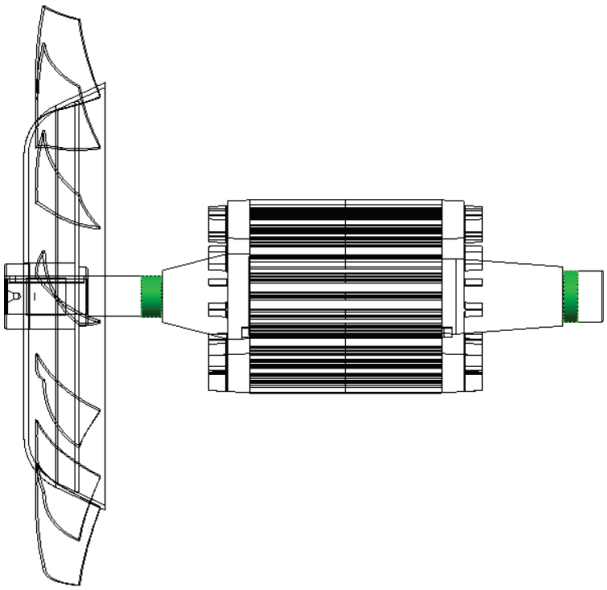

Fig. 1. Rotor model with bearing locations shown in green color

B. Input Data for the Rotor Dynamics Analysis

The parameters of the 'Rotor in AMBs' assembly related to the rotating and electromagnetic parts are presented in Table 2 (the bias current is varied for optimization purpose).

TABLE II. AMB and Rotor Properties

Component	Properties		
	Name	***Parameter***	***Value***
Electromagnet	Number of turns	N, [-]	88
	Pole cross-sectional area	A, [mm^2]	675
	Angle between poles	2θ, [deg]	45
	Bias current	i_b, [A]	4..8
Actuator	Gain	k_i, [N/A]	388..777
	Nominal stiffness	k_s, [MN/m]	5.74..23
	Nominal air gap	s_0, [mm]	0.25
Rotor	Mass	m, [kg]	161
	Diametral mass MOI[a]	I_d, [kg*m^2]	7.154
	Polar mass MOI[a]	I_p, [kg*m^2]	2.445
	Location of COG[a]	x_{COG}, [mm]	337.32
	Front bearing diameter	D_f, [mm]	55
	Rear bearing diameter	D_r, [mm]	69.4
	Bearing span	x_b, [mm]	594
	Target bearing stiffness	k_t, [MN/m]	11..44
	Rated speed	Ω_{rated}, [rpm]	3000

[a] MOI – moment of inertia; COG – center of gravity.

These parameters in addition to the transfer functions presented in Table 1 are used in the calculations of the dynamic response of the 'Rotor in AMBs' assembly.

C. Calculation Model of the Rotor in AMBs

The three-dimensional finite-element (FE) model shown in Figure 2 was created to calculate the dynamic response of the rotor in active magnetic bearings modeled as spring-damper elements using stiffness and damping coefficients.

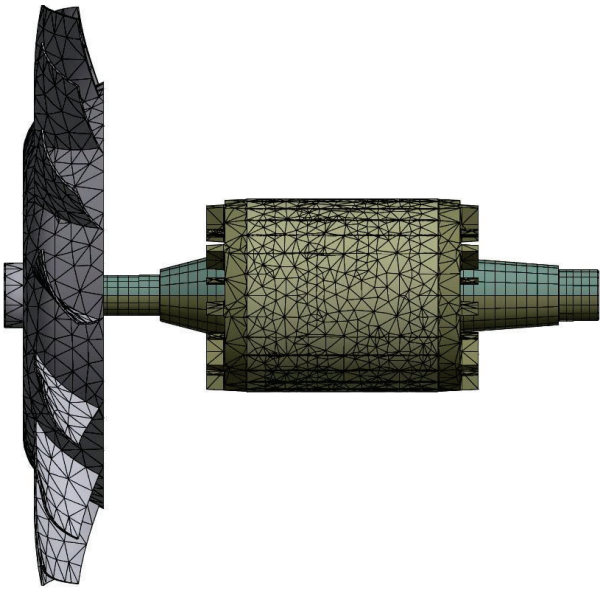

Fig. 2. Finite-element model of the rotor used for calculation

The geometrical model of the rotor was modified by simplifying the parts less important for the rotor dynamics response as a main focus of the study to reduce the FE model size having 243175 nodes and 135623 quadratic finite elements of tetrahedron, pyramid and hexahedron shape with special attention to the swept mesh creation for the shaft as the most responsible part of the rotor dynamics response and free mesh for the lumped elements which in the same way as the mapped one can represent their distributed mass-inertia properties correctly (the mesh error is less than 2%).

As per assessment made in [5], the front and rear bearing reactions were about 1000 N and 500 N respectively which required the appropriate electromagnet selection to provide the corresponding bearing capacity. The source [27] presented an in-depth study of the rotor in AMBs with the electromagnets having the bearing capacity of 2400 N which satisfied the requirements for the current rotor. Based on this, the majority of parameters presented in Table 1 and Table 2 were selected according to this source with some tuning for the size and modal characteristics of the investigated design. This refers to the use of the second-order low-path filter to cut off the first free-free backward whirl critical speed of the rotor equal to 113 rotations per second.

IV. Results and Discussion

A. Stiffness and Damping of AMBs

Although the rotor rated speed is 3000 rpm, stiffness and damping coefficients of active magnetic bearings were calculated up to 10000 rpm to give the insights of the possible resonances due to the presence of rigid body modes and for different values of bias current to find the optimal parameters of the AMBs. Figure 3 presents the dependence of these coefficients on rotor rotational speed (RS). This dependence is used for calculation of rotor critical speeds as spring-damper element direct stiffness and damping coefficients.

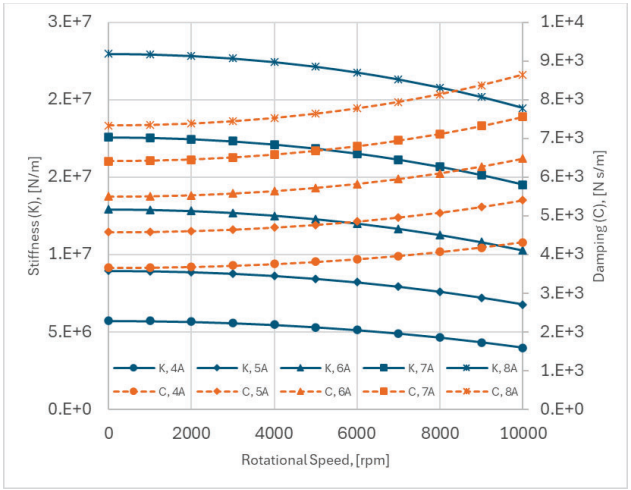

Fig. 4. AMB stiffness and damping vs RS for i_b = 4 A..8 A

B. Rotor Dynamics Response in AMBs

As mentioned in the previous paragraph, the calculation of AMB stiffness and damping was performed for variable bias current which allowed determining the backward whirl (BW) and forward whirl (FW) critical speeds (CS) of the rotor for this variation shown in Figure 4 and, as a result, the required value of the bias current to have no resonances within the rotational speed range.

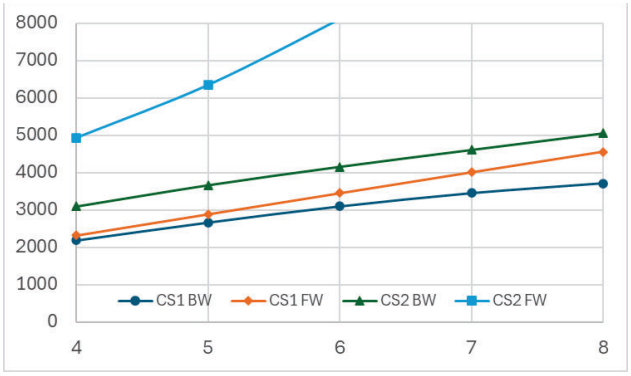

Fig. 3. First two BW and FW critical speeds, [rpm] vs bias current, [A]

As it follows from the figure, the bias current of 8 A results in the 20% margin of the first backward and forward whirl critical speeds above the rated speed of the rotor which makes it rigid (no resonances occur during rotor startups and shutdowns). Figure 5 shows the Campbell diagram for this value of bias current with the corresponding mode shapes.

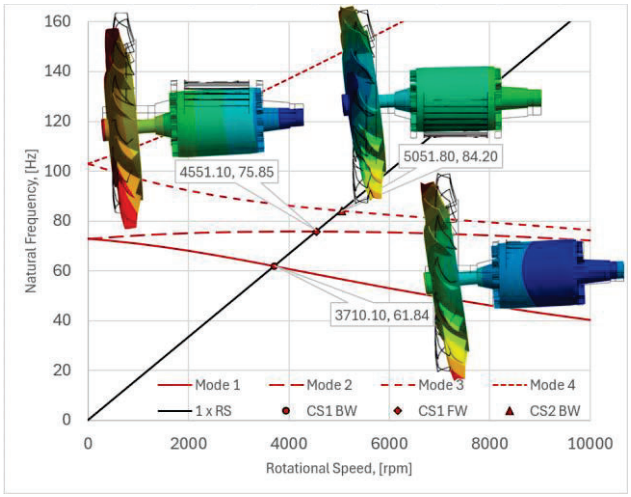

Fig. 5. Campbell diagram for AMBs with stiffness and damping coefficients identified for i_b = 8 A

The first BW and FW critical speeds associated with combined rigid-flexible body modes are about 3710 rpm and 4551 rpm respectively which allows concluding that the use of AMBs with selected parameters in the rotor results in its non-resonant operation for its whole rotational speed range.

V. Conclusion

The paper presented an approach which allows identifying the active magnetic bearing stiffness and damping coefficients for their use in rotor dynamics calculations intended to justify the possibility of AMB implementation in the existing rotary machine for increasing its efficiency which had a decrease due to ineffective operation in rolling element bearings. The approach is based on the consideration of the AMB component dynamics in the form of the corresponding transfer functions. The results of the rotor dynamics response of the machine installed in the active magnetic bearings with a SISO PID control and other parameters specially tuned for the considered design indicate the non-resonant operation of the industrial fan rotor in AMBs which enables further use of these bearings for increasing the efficiency of the considered fan by approximately 10% due to switching from the rolling element bearings with high friction to the frictionless AMBs.

***Abstract*—The dependence of coke resistivity on the component composition of the coal batch and the final process temperature was confirmed. Given that the resistivity and reactivity are affected by some common factors, such as temperature and coke readiness, which indicates the orderliness of its structure, the relationship between these indicators was confirmed. The resistivity is an aggregate indicator of coke properties, the values of which are determined by the ash, sulfur content, volatile matter, petrographic composition and carbonization conditions of coal raw materials. In the course of research, a comprehensive selection and study of components included in the raw material base of coking of coke production was carried out. According to the results of technical, plastometric, petrographic analyses of the studied coals recommendations on their rational use in the batch of the enterprise were given. These recommendations have been tested by pilot coking, according to the results of which the proposals on providing rational temperature regime of their coking have been given.**

Keywords—electrical resistivity, petrographically heterogeneous inter-basin coal batch, coke structure, process temperature, coke reactivity index.

I. INTRODUCTION

At present, blast furnace production sets higher requirements to coke quality, the standards of which are fixed both in the current technical specifications (A^d, S^d_t, M_{10}, M_{25}) and in ISO 18894-2006 (CRI and CSR). Thus, the current requirements for coke quality are $M_{25} \geq 88.0\text{-}90.0\%$; $M_{10} \leq 6.0\text{-}6.5\%$; CSR – 60.0-75.0%; CRI – 25-30.0 %.

Analysis of coal resources shows that domestic raw material base is not able to provide production of blast furnace coke of improved quality on its own. As a consequence, the question of attraction and rational use of imported components (coals from far abroad) in coal batch for coking arises [1].

Classification of distant foreign coal and its aggregation into classes and groups [2,3] differs from the accepted classification of grades in accordance with DSTU 3472-2015.

Therefore, it is obligatory to formulate the coal mixture taking into account the maceral composition, the indicator of vitrinite removal and the distribution of vitrinite components by stages of metamorphism, the optimal ratio between clinkering (ΣCC) and lean (fusinized) components (ΣFC). When predicting the output and properties of coke, we should take into account that the macerals of the groups of vitrinite, liptinite and 1/3 of semivitrinite constitute the sum of reactive and clinkering components, while the whole of inertinite and 2/3 of semivitrinite have an oppressive effect on the system as a whole [4].

In order to determine the optimal conditions for preparation and coking of batch with a large content of petrographically heterogeneous coal in laboratory and experimental-industrial conditions, studies were conducted to determine their rational grade and component composition, preparation schemes, coking mode, as well as to assess the impact of these measures on the quality of blast furnace coke (in terms of mechanical strength, specific electrical resistance).

Carrying out the above measures is especially relevant in the conditions of coke-chemical enterprises of Ukraine, the raw material base of which contains coals of different basins.

II. MATERIALS AND METHODS

Samples of the production batch. Component composition of the batch was as follows: A-10%. E-11%, B-8%, F+G+H-10%, D-35%, C-26%. The technological properties and petrographic characteristics of these samples were determined.

The characteristics of the coal concentrates were determined according to the following standard methods: ISO 1171-97 “Solid mineral fuels. Methods for determination of ash”; ISO 589-81 “Hard coal –

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

Determination of total moisture"; ISO 7404-3-84 "Methods for the petrographic analysis of bituminous coal and anthracite - Part 3: Method of determining maceral group composition"; ISO 7404-5-85 "Methods for the petrographic analysis of coals–Part 5: Method of determining microscopically the reflectance of vitrinite"; State standard of Ukraine 7722:2015 "Hard coal. Method of determining plastometric characteristics".

Basic batch	10.4	0.83	26.5	29.6	34	13

TABLE III. PETROGRAPHIC CHARACTERISTICS OF COAL BATCH

Sample	Petrographic composition (without mineral impurities), %					Mean vitrinite reflection coefficient, %
	Vt	Sv	I	L	∑ FC	R_o
Basic batch	74	1	22	3	23	1.07

The production batch of the plant has increased ash (A^d=10.4%) compared to the batch of other plants of Ukraine, where ash of the batch, as a rule, varies within 8.5-9.0%. Sulfur content in the batch is low (S_t^d= 0.83%). It should be noted that the composition of the batch vitrinite includes coals of almost all stages of metamorphism from from low-metamorphosed to highly metamorphosed. The main amount of vitrinite constituents vitrinite constituents have reflection coefficient R_o values in the range of 0.65-0.84 (20%) and 0.90-1.19 (59%).

The total content of vitrinite constituents corresponding to coals Zh and K grades amounted to 66%. However, taking into account that the absolute content of vitrinite in the batch is only 74%, the actual amount of vitrinite components having a reflection index of 0.9-1.39%, in the organic mass amounted to only 46.9%, which is far enough from the recommended minimum value of 53%, which ensures the production of high-strength metallurgical coke. Reduced amount of well clinkering components of vitrinite and increased content of non-clinkering macerals of inertinite group, as well as high ash, caused low sinterability and coking ability of the batch as a whole, which was reflected in the results of the study of plastic and viscous properties of the batch.

The variants of pilot batches were developed to test them by box coking (batches1-3). The grade and component composition of the pilot batches, as well as petrographic characteristics of coals and batches are given in Table 4. At development of variants of experimental batches we were guided by the fact that first of all it was necessary to reduce the content of non-binding macerals of inertinite group in experimental batches in comparison with the basic one, first of all at the expense of coal H. Also, it is necessary to exclude from the batch coal F, which actually does not contain vitrinite with reflection index 1.2-1.39, and has in its composition an increased number of components, with R_o=0.65-0.84%, R_o=0.90-1.19% and R_o=1.7-2.59%. Introduction of petrographically homogeneous H coal into the batch, as well as increase in the content of E and A coal, which have the minimum content of inertinite group macerals, also contributes to the solution of the above problems.

TABLE IV. PETROGRAPHIC CHARACTERISTICS OF COAL SAMPLES AND BATCHES

Sample	Petrographic composition (without mineral impurities), %					Mean vitrinite reflection coefficient, %
	Vt	Sv	I	L	∑FC	R_o
A	85	-	12	3	12	0.69
B	73	-	23	4	23	0.93
C	79	-	20	1	20	0.94
D	91	-	8	1	8	1.06
E	89	1	8	2	9	1.31
F	76	3	21	-	23	1.14
G	38	2	60	-	62	1.28
H	89	1	10	-	11	1.53
Basic batch	74	1	22	3	23	1.07
Batch 1	79	-	20	1	20	1.00
Batch 2	78	1	19	2	20	1.05
Batch 3	80	1	18	3	18	1.1

The content of fusinized macerals (ΣFC) in the experimental batch compared to the base batch decreased from 23% to 19-20%. The amount of vitrinite components with a mean vitrinite reflection coefficient of 0.9-1.39% in organic mass increased from 45.1% in the base batch to 51.4, 49.9 and 48.8%, respectively, in the experimental variants.

Box coking was carried out according to the following methodology. Experimental batches weighing 5.5 kg were loaded into metal crates. With the crate volume of 7.3 dm^3, the density of the experimental batch in them was approximately 0.760 t/m^3, that is, it corresponded to the average practical data on the density of the batch in the chamber. Photos of the boxes are presented in Figure 1.

Coking of experimental batches was carried out on coke batteries (effective volume of the chamber 21.6 m^3) in specially selected ovens with good condition of masonry of heating partitions and stable thermal regime.

Fig.1. Metal boxes for coking of pilot batches

Loading of boxes was carried out through the middle hatch after the release of batch from the coke and machine hoppers of the coal loading car, so that the boxes with batch were located at a level of approximately 2.5 m from the bottom of the coking chamber, that is, in the zone of optimal temperature conditions. Four boxes were loaded into each chamber, according to the number of experimental batches. Experimental coking was carried out under the thermal regime, the parameters of which are presented in Table 5.

TABLE V. COAL BATCHES COKING CONDITIONS

Coking period, hours	Temperatures in the control verticals, °C		Coke cake axis temperature, °C
	machine side	coke side	
15.5	1320	1350	1035

Once the coking process was complete, the coke cake was delivered using standard technology (from the chamber to the quenching car, then quenching and unloading onto the coke slide). If necessary, the boxes were quenched with water and pre-cooled in air.

The obtained experimental coke was extracted from the crates, weighed and dried to constant weight to determine the yield of gross coke from the batch and subsequent analyses (proximate analysis, mechanical strength, thermochemical properties). The characteristics of the obtained cokes (indicators of proximate analysis, physical and mechanical properties, thermomechanical properties) were determined according to the following standard methods: ISO 556-80 “Coke (greater than 20 mm in size)-determination of mechanical strength”; ISO 18894:2006 “Coke-determination of coke reactivity index (CRI) and coke strength after reaction (CSR)”.

Additionally, to characterize the orderliness of the structure of coke and the degree of their readiness determined the specific electrical resistance for DSTU 8831:2019 Coke. Method for determination of the resistivity of coal coke powder, which establishes a method for measuring the resistivity of coal coke powder in the range from 0.05 Om·cm to 0.5 Om·cm. The results of studies of experimental coke are shown in Tables 6 and 7.

III. RESULTS AND DISCUSSION

As can be seen from the given data, ash of basic and experimental coke is high and varies within 12.6-12.9 %. At the same time, sulfur content is low and varies in the range of 0.52-0.61%.

The ashing coefficients depend on the yield of volatile substances from the batch, decreasing at lower yield and increasing at its increase. The coefficient of residual sulfur in coke is within the range of 0.800-0.869.

TABLE VI. QUALITATIVE INDICATORS OF BOX COKING COKE AND ASHING AND DESULPHURIZATION COEFFICIENTS

Sample	Proximate analysis, %			Ashing coefficient	Desulphurization coefficient	ρ, Om·cm
	A^d	S_t^d	V^{daf}			
Basic	12.9	0.61	0.9	1.303	0.806	0.0597
Batch 1	12.9	0.53	0.6	1.330	0.815	0.0568
Batch 2	12.6	0.52	0.5	1.299	0.800	0.0562
Batch 3	12.8	0.53	1.1	1.312	0.869	0.0547

TABLE VII. QUALITATIVE INDICATORS OF COKE

Sample	CRI, %	CSR, %	Yield and strength of coke, %		
			Yield	M_{25}	M_{10}
Basic	38.3	40.5	76.31	87.1	8.0
Batch 1	36.5	44.0	75.26	87.3	7.8
Batch 2	36.1	44.9	76.60	87.4	7.5
Batch 3	35.2	48.8	75.82	87.7	7.4

Electrical resistivity is a measure of temperature action during the thermal destruction of coal and coke conversion. Regardless of the final temperature of the process, the pithomium electric opir decreases the more the higher the temperature is. Therefore, the indicator of pithomic electric pressure can characterize the level of readiness of coke. Also, the readiness of the obtained coke is good, which is indicated by the data on the yield of volatile, the value of which is equal to 0.5-1.1%, and the value of specific electrical resistance, the values of which are within the range of 0.0547-0.0597 Om·cm.

Indices of reactivity CRI and post-reaction strength CSR, determined by the method of “Nippon Steel” were the worst for coke from the base batch, and the best values were obtained for coke from batch of variant 3. Coke from the batch of variants 1 and 2 is also better than coke from the basic batch, primarily due to the fact that F coal, which has an extremely high ash of 12.8%, was removed from the composition of the experimental batch. The results of thermochemical characteristics correlate with the data on the value of electrical resistance of coke, which corresponds to the results of studies presented by us in [5,6]. The established correlation between the coke electrical resistivity and reactivity and post-reactivity strength is logical. Coke electrical resistivity and reactivity are different for their nature. Thus, the analysis of many studies [7-10] shows that the CRI is influenced by the properties of the used coal (ash, content of sulfur, mineral content, yield of volatile substances, petrographic composition), the technology of batch preparation and heat engineering mode of its coking, and the period of coking. At the same time, both of these indicators change synchronously due to the fact that they are influenced by some combined factors, such as temperature level and coke readiness, which indicates the order of its structure.

The resistivity reflects the state of the carbon structure and the density of contact between the residual material of

the coal grains and the petrographic components that make up the organic mass of the grains. Consequently, coke produced from poorly coking and petrographically heterogeneous and high-ash coal is characterized by a higher resistivity. An increase in resistivity and reactivity indicates a decrease in the orderliness of the coke structure. Consequently, the reactivity of coke will increase with increasing electrical resistivity. Also, the electrical resistance decreases with increasing structural strength and abrasive hardness [11-14].

Based on the analysis of experimental data, a graph of the dependence of the specific electrical resistance of coke on the reactivity of coke (Fig.2), which is characterized by a high correlation coefficient, was obtained r = 0.84.

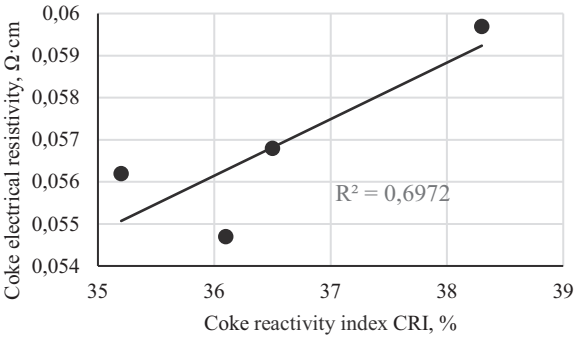

Fig.2. Relationship between the coke electrical resistivity and the coke reactivity index

The analysis shows that the best values of M_{25} and M_{10} have coke from charge of variants 2 and 3, which contain G coal.

Transition to batch coking without participation of G and F coals allows to noticeably improve mechanical strength indicators, as well as CRI and CSR indicators. Quality indicators of metallurgical coke were improved due to introduction of 10% H coal into the batch.

Thus, the minimum specific electrical resistance was recorded for variant 3 of the experimental batch, which is characterized by the minimum ash, sulfur content, maximum vitrinite content, and the value of the vitrinite reflection index [15].

IV. Conclusions

The experimental studies made it possible to formulate the following conclusions:

- petrographically heterogeneous and multi-basin raw material base causes certain difficulties in the development of rational compositions of coal batches, taking into account the conditions of their preparation and coking to obtain blast furnace coke of stable quality;
- based on the results of pilot coking of scientifically based compositions of coal batches developed with the participation of imported coal, three variants of coal batch compositions were proposed, the coke from which has better quality indicators.

Thus, it was found that changing the component composition of the coal batch by increasing the content of highly metamorphosed coal, as a result, causes an increase in the vitrinite reflection index, and also leads to an increase in the orderliness of the coke structure and a decrease in its specific electrical resistance.

It has been shown that when optimizing the component composition of coal blends, it is necessary to take into account the value of the electrical resistivity of coke, which depends on the ash, volatile matter, petrographic composition, and vitrinite reflectance.

It should be noted that the use of the coke electrical resistance test to optimize the component composition of blends and monitor coke quality in a particular coke production is practical and economically feasible. Since the electrical resistance determination is simpler, does not require reagents, and takes much less time than the reactivity test. Therefore, it can be considered an operational method for determining the structural characteristics and readiness of coke.

***Abstract*—This paper investigates the potential of residential electric storage water heaters (ESWHs) to provide demand-side flexibility in modern power systems. To capture both physical and behavioral aspects of ESWH operation, a thermophysical simulation in OpenModelica is integrated with an agent-based behavioral simulation of hot water usage using the Load Profile Generator (LPG). We propose, for the first time, the Reserve Coefficient of Aggregated Portfolio (RCAP) as a novel metric to quantify the availability and controllability of aggregated flexibility in ESWH portfolios. The RCAP framework enables precise quantification of flexibility, linking technical availability with market-oriented decision-making and supporting strategic planning for aggregators and grid operators. The approach generates realistic and diverse demand profiles across different household types, capturing daily and weekly variability, and validates them against empirical consumption patterns. Aggregation is modeled by simulating market participation, segmenting households into representative groups, and estimating baseline consumption for aggregated loads. The RCAP metric further quantifies the thermal availability and controllability of the ESWH portfolio over time. Collectively, these contributions provide a robust basis for integrating ESWHs into demand response programs, enhancing both operational efficiency and market value.**

Keywords—electric storage water heaters, hot water demand profiles, residential demand response, consumer portfolio aggregation, demand side flexibility, aggregator strategy

I. Introduction

In contemporary power systems, integrating variable renewable generation and ensuring grid reliability require both technical and managerial innovations in demand-side flexibility. Residential ESWHs, when aggregated and intelligently controlled, represent a significant source of controllable load that can support balancing services, improve resource utilization, and enable new business models for aggregators, energy service companies, and grid operators.

A precise estimation of the flexibility potential of ESWHs, along with the system-level implications of their activation, requires detailed modeling of end-user behavior, particularly realistic hot water usage patterns and the resulting load profiles. Ignoring the diversity and stochasticity of user behavior can lead to substantial errors in flexibility forecasting and, more critically, in predicting the timing and magnitude of rebound effects that may threaten grid stability.

From a strategic perspective, accurate ESWH modeling is not only a matter of technical precision but also a foundation for informed decision-making. Aggregators rely on such modeling to design optimal bidding strategies, manage portfolio composition, and target specific consumer segments for participation in demand response (DR) programs. Load profiles serve as essential instruments for understanding user behavior, optimizing energy resource allocation, and facilitating DR integration. At the same time, advanced data analytics and automated control algorithms enable tailored activation strategies that maximize participation while preserving user comfort.

Several methodological approaches exist for modeling ESWH operation, including analytical, statistical, and simulation-based techniques. Analytical models, grounded in thermodynamic and electrical differential equations, offer detailed insights but fail to capture behavioral variability. Statistical models use historical consumption data to forecast usage via regression or machine learning, providing adaptability but relying on data quality. Simulation-based methods, particularly agent-based modeling, integrate heterogeneous consumer behaviors and system interactions, producing realistic and granular consumption profiles suitable for strategic flexibility planning.

This study aims to analyze ESWH load profiles in residential contexts, identify characteristic consumption patterns under different operational regimes, and introduce the RCAP as a decision-support tool for technology management in distributed energy systems. The proposed framework links behavioral and physical modeling to inform optimization, planning, and innovation strategies for real-world DR programs and market participation. Furthermore, the incorporation of socio-demographic profiling ensures that demand response planning reflects realistic household diversity, enhancing both the technical robustness and the strategic value of the proposed approach. This integration enables stakeholders to directly translate modeling results into effective operational and market strategies.

II. Simulation of ESWH Usage

A. Analysis of Hot Water Demand Models

Studies [1] have demonstrated that household electricity demand exhibits a strong temporal dependency, closely aligned with residents' daily routines and lifestyle patterns. The use of ESWH is particularly related to occupants' work and rest schedules, as evidenced by time-use data. Findings in [2] indicate that the return-home time of residents significantly contributes to evening peak electricity demand, a factor that must be incorporated into demand-side management strategies.

A promising direction of research involves the use of behavioral models that capture the intra-day distribution of load. In [3], neural networks were applied to forecast long-term shifts in household behavior and their corresponding

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

impact on electricity consumption, enabling peak load shifting and improved system optimization. Agent-based approaches are particularly valuable in this context, allowing for the simulation of appliance usage scenarios based on behavioral models that incorporate both habitual practices and external influences such as tariff changes and renewable energy integration.

Stochastic models have also been widely used in residential water consumption modeling. One such model, the Stochastic Residential End-use Model (STREaM) [4], generates high-resolution synthetic time series of water usage based on the operational characteristics of individual fixtures, including frequency, duration, and time-of-day patterns. STREaM supports scenario analysis and impact assessment under varying consumer behaviors and management policies.

Despite its advantages, STREaM lacks flexibility in adjusting parameters to account for household-specific behaviors or socio-economic differences, limiting its applicability in customized settings. Additionally, research [5] has shown that while high-frequency sampling improves anomaly detection and end-use disaggregation, it also imposes greater demands on data storage and processing. These limitations highlight the need for adaptive modeling techniques, with agent-based models offering a promising way to incorporate behavioral heterogeneity.

Over the past decades, numerous methods have been proposed for generating household electricity load profiles. However, most stochastic models fail to represent realistic human behavior. The modeling tool LPG, developed by Noah Pflugradt [6], introduces an agent-based modeling approach grounded in the theory of human needs, initially proposed by D. Dörner [7]. In contrast to traditional probabilistic models, LPG assumes that individuals act to minimize deviation from an internally defined comfort level.

LPG simulates residential electricity and water demand by emulating occupant behavior. Each simulated household follows predefined routines and behavior patterns, resulting in dynamic appliance use and energy consumption. This allows LPG to generate plausible high-resolution load curves for electricity, hot and cold water, and occupant activities, which can be exported as CSV files for further analysis.

Among its core strengths, LPG allows detailed configuration of household, including family structure, employment status, lifestyle routines, appliance availability, and location (urban vs rural). The load profile is shaped by environmental, demographic, and behavioral inputs:

1. Environmental: season, ambient temperature, daylight duration;

2. Demographic: household size, working hours, hobbies;

3. Behavioral: meal schedules, comfort preferences, energy-saving awareness.

This level of customization supports the creation of plausible, scenario-specific profiles.

Most importantly, besides electricity consumption models of various appliances, the LPG includes a hot water demand model built on the same behavioral principle.

B. Agent-Based Modeling of Hot Water Demand

At the core of the LPG hot water demand model is the behavioral representation of users. The basic concept is that several devices offer different activities to the person. The person checks the expected satisfaction of desires from each activity and chooses the one that promises the greatest satisfaction at a given time. In turn, every desire is specified by its weight (importance), threshold, and decay of importance.

Thus, the load or consumption of an energy resource, such as hot water, by household $E(t)$ can be described as

$$E(t) = \sum_{n} \sum_{i} E_i\left(t, A_n^c(t)\right), \tag{1}$$

where n is the person number; i is the device number; A_n^c is the current activity of the n-th person; E_i is the energy consumption profile of the i-th device.

$$A^c(t) = \underset{\{A_j\}}{\arg\max}\, F_S\left(t, A_j(t), \{D_k, w_k, h_k\}\right), \tag{2}$$

where F_S is the satisfaction function; A_j is the j-th possible activity; D_k is the value of the k-th desire; w_k is the weight of the k-th desire; h_k is the threshold of the k-th desire.

The value of desire decays (expires) with time:

$$D(t+1) = e^{\left(\frac{\ln 0{,}5}{T_d}\right)} D(t) \tag{3}$$

where T_d is the decay (half-life) of the desire.

A person's desires also depend on many specific factors such as age, social status, habits, as well as the day of the week, the season, the general characteristics of the household, etc. And they need to be described carefully and completely to obtain a plausible load profile.

For the research topic, hot water flow rate is a key variable. While the maximum flow is determined by the capacity of the equipment, the actual rate is influenced by user desires and actions, such as when the tap is turned on or off, or how the water temperature is adjusted. Compared to other modelling approaches, LPG can plausibly reflect user behavior and generate high-resolution profiles of hot water demand over time, and importantly, it allows for the description of almost arbitrary households. This makes it a powerful tool for estimating household energy use, supporting the design of adaptive demand response and flexibility market mechanisms.

Hot water usage profiles exported from LPG in CSV format can serve as input data for the model of ESWH electricity consumption running on external simulation platforms. In our previous work [8], the OpenModelica modeling and simulation environment was used to implement a detailed physical model of ESWH and simulate its operation modes. This model incorporates heat transfer dynamics, thermostat control logic, and tank thermal capacity, allowing calculation of electricity consumption based on hot water draining rate, inlet water temperature, ambient losses, and heating element characteristics.

The combination of behavior-driven water usage modeling with thermophysical ESWH simulation enables an accurate estimation of ESWH electric energy consumption. First, a baseline consumption profile, i.e., without any external control, is calculated. The aggregate baseline of

multiple ESWHs represents a reference for flexibility interventions. This then enables the analysis of different energy management strategies for demand-side flexibility, and demand forecasting across different time scales and population groups for energy system operation optimization.

C. Validation of Hot Water Demand Profiles

A crucial step in the selection of a hot water demand model is the verification of the generated daily profiles, especially for water heated to 40°C. In the study, this is done by corresponding with measured electrical load profiles of real ESWHs. This should provide an assessment of the accuracy of the hot water demand model and identify fundamental deviations from the real ESWH operating modes if they are.

As shown in the study of energy demand and rhythms of everyday life [9], hot water consumption closely follows human activity rhythms, with peaks typically occurring in the morning 6:00–9:00 and evening 18:00–22:00. These periods coincide with daily routines such as showering and cooking, placing greater load on the energy system and emphasizing the need for demand-side flexibility. Consumer behavior, and in particular hygiene habits, play a key role in shaping hot water demand, which also exhibits clear seasonal variability. Real-world studies [10] indicate that the average European consumes 40–50 liters of hot water daily, with winter usage increasing by 15–25% compared to summer due to colder ambient temperatures.

For the verification, a household was selected from LPG that closely matches the real-life test case. Computer modeling of the ESWH operation was carried out in OpenModelica. At the first stage, daily hot water demand profiles generated by LPG were converted and imported into OpenModelica. Then, using a thermodynamic model that accurately represents the temperature stratification of water in the tank and the heating element control algorithms [8], the instantaneous load of the ESWH electricity consumption was calculated. Fig. 1 illustrates the historical and simulated electrical power and water demand profiles for winter and summer periods, respectively.

During the winter season, both electricity and hot water consumption exhibit a clear daily pattern, with distinct peaks reflecting household activity. Between 00:00 and 06:00, consumption remains low due to minimal activity. A sharp rise occurs between 06:00 and 07:00, corresponding to typical morning routines such as showering, cooking, and appliance use. During this time, normalized power reaches 60%, and hot water usage significantly increases. After the morning peak, demand gradually declines and remains relatively stable until 16:00–17:00, followed by another rise during evening hours 18:00–22:00. Although the model slightly underestimates the evening peak, the total simulated electricity consumption (9.93 kWh for the test ESWH with rated power of 1.2 kW) closely matches the experimentally measured value (10.02 kWh). Simulated hot water usage of 227.89 liters is also very close to observed data, demonstrating LPG model accuracy.

Winter patterns are easier to model due to their predictability and routine nature. In summer, electricity use is significantly lower due to reduced heat losses and changes in user behavior. While a morning peak is still present, it is less pronounced, reflecting altered daily routines and a lower need for hot water. Daily energy demand remains low, and the evening peak is also less defined. The model shows some deviation (measured electricity use for the test ESWH is 3.54 kWh compared to the simulated 4.51 kWh). This may be due to external factors not captured in the model. Summer hot water consumption drops to 187.70 liters, confirming seasonal variation. Despite this, it can be concluded that the ESWH model, together with hot water demand profiles generated by LPG, generally reflects all the key trends of real electrical load profiles.

III. CONSUMER AGGREGATION

A. Market Aggregation Processes

Electricity consumer aggregation for DR can be generally categorized into three main process groups:

1. Resource Formation for Aggregation: This includes the identification and registration of participants, grouping into aggregation units, and equipping installations with demand-side management devices;

2. Development of Aggregation Products: This involves registering aggregation units as resource entities, obtaining ancillary service provider status, collecting telemetry, forecasting individual consumption, and generating load profiles.

3. Market Implementation: This includes submitting planned schedules, bidding in auctions, and executing load control in response to Transmission System Operator dispatch instructions. It also covers metering and monitoring operations.

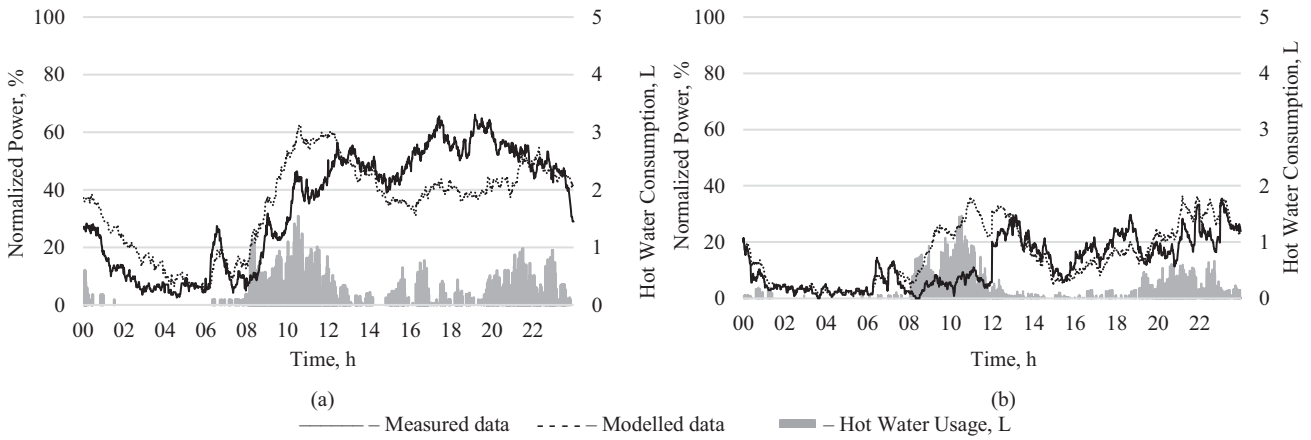

Fig. 1. Power and hot water demand profiles during winter (a) and summer (b)

The process of product development and market implementation is inherently cyclical, driven by fluctuations in demand, price, and system needs. Aggregator must continuously update forecasts, adjust load schedules, and resubmit bids accordingly. At this stage, the use of generated water demand profiles, which are generally stochastic but consistent with real experience, as well as derived load profiles is crucial for realistic modeling of consumers DR. These profiles must capture the variability in baseline demand and enable accurate simulation of ESWH flexibility, which depends on thermal state shaped by past water use. Second, they must support accurate modeling of ESWH response to control signals, as flexibility availability depends on the current thermal state defined by tank temperature, thermostat setting, and also water drain. Equally important, plausible and diverse profiles are essential for quantifying rebound effects, which are governed by the accumulated thermal deficit and its heterogeneity across ESWHs, ultimately determining the shape, amplitude, and duration of load recovery peaks.

B. Consumer Group Profiling

A fundamental prerequisite for the effective implementation of demand-side management programs is a deep understanding of end-user behavioral patterns. This extends beyond the technical characteristics of ESWH to include usage behavior shaped by socio-demographic factors, daily routines, and work schedules.

With the LPG modeling tool, 25 daily ESWH consumption profiles were stochastically generated for 6 types of households, representing a range of socio-economic scenarios. Each profile reflects the behavior of an individual user during a typical working day in the autumn season, in the absence of external DR control signals.

To obtain representative daily electrical load profiles, the profiles within each group were averaged. All calculations were performed in relative units, enabling analysis of load dynamics independent of absolute power. Each value was normalized to the rated power of the ESWH, resulting in a time-dependent normalized load profile, $P_n(t)$, expressed as a percentage.

$$P_n(t) = \frac{1}{N}\sum_{i=1}^{N}\frac{P_i(t)}{P_{r,i}} \times 100\%, \qquad (4)$$

where $P_i(t)$ is the power consumption of the i-th ESWH at time t, in watts; $P_{r,i}$ is the rated power of the i-th ESWH, in watts; N is the number of individual profiles in the group; t is time of day, in minutes (from 1 to 1440).

An analysis of the normalized ESWH load profiles for various socio-demographic household types reveals clearly defined behavioral patterns. Households with two working adults (Fig. 2a) exhibit a distinctive double-peak profile, with morning and evening peaks aligned with standard working hours. Unemployed couples (Fig. 2b) show a more temporally extended and less intense patterns of use. The highest overall consumption is observed in families with three children and working adults (Fig. 2c), characterized by a broad evening plateau, which presents a promising opportunity for load shifting. A similar household without employed members (Fig. 2d) demonstrates significant midday activity, indicating a potential flexibility window during periods of renewable energy surplus. Single working adults (Fig. 2e) have less distinct peaks, while unemployed singles (Fig. 2f) display smoother, more predictable profiles with activity concentrated in the first half of the day.

Classifying consumers by household type allows aggregators to design targeted load optimization strategies that integrate both technical feasibility and behavioral compliance. In this context, each household type should be treated as a distinct response unit, capable of engaging with dispatcher signals differently depending on the time of day and user habits.

C. Baseline Load Modeling for Aggregated Loads

To analyze the operation of a portfolio under aggregated load management, a coefficient of activity K_{act} is introduced. It is equal to the normalized sum of load profiles of all ESWH participating in DR. That is, $K_{act}(t)$ represents the share of the aggregated rated (installed) capacity of the ESWHs that are actively used at a given time t.

$$K_{act}(t) = \frac{\sum_{i=1}^{N_{act}} P_{act,i}(t)}{\sum_{i=1}^{N} P_{r,i}} \times 100\%, \qquad (5)$$

where $P_{act,i}(t)$ is the actual power of ESWH in the portfolio, which is in active operation at time t.

Fig. 3 shows $K_{act}(t)$ for a portfolio of 425 simulated consumers covering a broad spectrum of socio-demographic categories, ranging from families with children to retirees

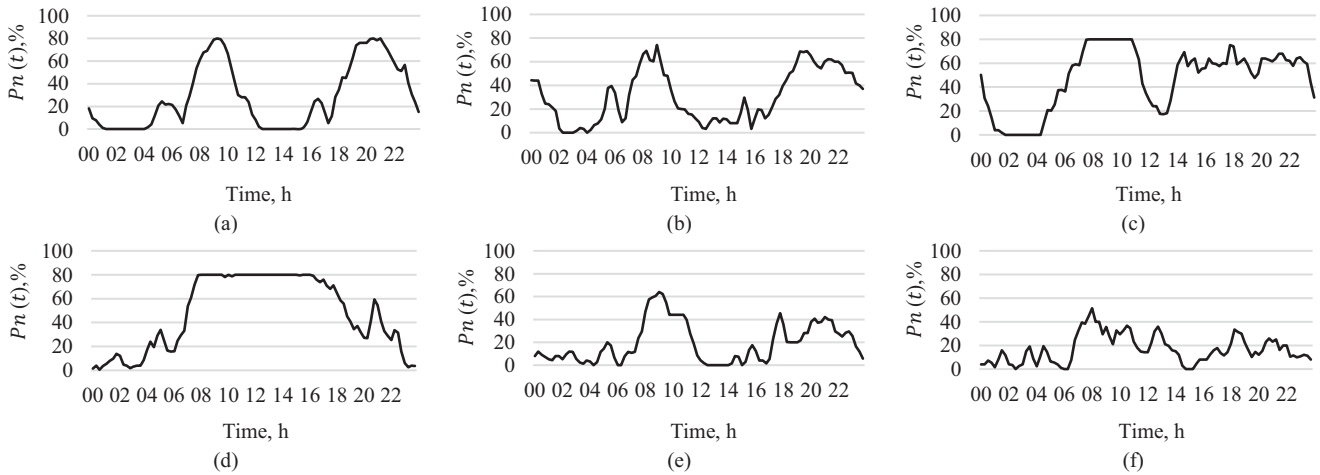

Fig. 2. Normalized ESWH load profiles: (a) Two working adults; (b) Two unemployed adults; (c) Two working adults with three children; (d) Two unemployed adults with three children; (e) Single working adult; (f) Single unemployed adult

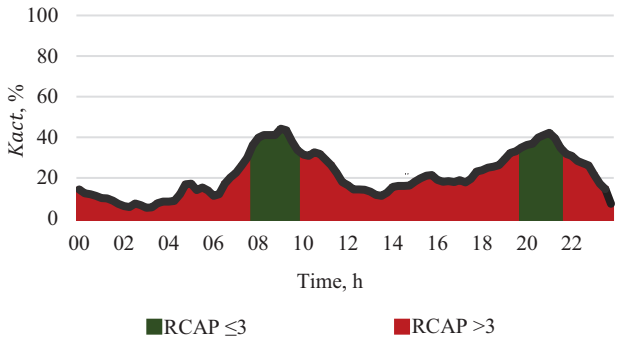

Fig. 3. Coefficient of activity of the portfolio

and shift-working households. In total, 12 household types were modeled, each represented by 25 to 50 individual consumption profiles. Each household was modeled with identical ESWH units rated at 1.2 kW and 80 liters. The resulting aggregate profile corresponds to a weekday in the autumn period.

The coefficient of activity of this portfolio exhibits a smoother consumption pattern compared to individual curves, reflected by a reduced peak-to-average ratio due to the averaging of individual peaks. The load factor is higher, indicating more consistent utilization throughout the day, while the form factor decreases as a result of more uniform load distribution.

To reliably deliver a certain power level as a flexibility service in the market, an ESWH aggregator must have some reserves in the portfolio. Lower levels of K_{act} require proportionally higher rates of reserve to maintain equivalent service delivery. This can be described by the RCAP K_{res} defined as:

$$K_{res}(t) = \frac{1}{K_{act}(t)} \quad (6)$$

This study finds that aggregator performance is optimal when RCAP ≤ 3. RCAP enables quantitative assessment of flexibility, availability, and reliability, guiding market participation strategies and supporting segmentation of consumer groups for targeted control within the portfolio.

A detailed analysis of the aggregated ESWH load profile reveals key insights into consumption patterns and flexibility. From 05:00, user activity increases gradually, peaking between 09:00–10:00, when up to 45% of the total ESWH capacity is used. This synchronized morning peak, driven by workday routines, shows the highest load utilization and lowest RCAP ≈ 2.5.

After the peak, a sharp decline in activity offers opportunities for short-term load reduction or shifting with minimal comfort impact. From 11:00–16:30, ESWH usage stays low at 15–20%, resulting in a high RCAP 5–6, allowing for increased load by providing preheating, which functionally acts as an energy storage device.

In the evening, demand rises gradually, peaking from 19:30–20:30, so RCAP ≈ 2,5, but increased variability in user routines reduces predictability and complicates management. Overnight (00:00–05:00), demand drops to 5–10%, pushing RCAP up to 10. Thus, this period is ideal for absorbing excess generation and smoothing the nighttime load curve through incentives.

Conclusions

This study demonstrates that integrating agent-based hot water usage modeling with thermophysical simulation of ESWHs produces realistic, validated load profiles across diverse socio-demographic groups. The introduction of the RCAP metric provides a quantifiable measure of portfolio flexibility, availability, and reliability, supporting the identification of optimal market participation conditions.

This capability allows aggregators and energy service companies to align operational strategies with broader innovation objectives, such as developing scalable demand response portfolios and enhancing customer engagement. The modeling outputs can inform innovation strategies in real-world DR programs by revealing when and how to activate specific consumer segments, designing targeted control schemes, and structuring market offers that maximize both technical performance and economic value.

For stakeholders, these insights extend beyond system operation, offering guidance for long-term portfolio planning. By linking behavioral diversity with measurable technical potential, the proposed framework supports strategic decision-making in the evolving flexibility services market. The model assumes uniform technical specifications for all ESWHs and ideal communication reliability between devices and control systems. It does not account for heterogeneous installation conditions, varying user comfort preferences, or potential delays in demand response activation. Future research should include field validation under real operating conditions and explore real-time optimization algorithms for portfolio management.

***Abstract*—This work presents an analysis of the electromagnetic properties of a planar metamaterial composed of elements made from two natural materials: ferrite and a nanostructured TiO_2-based semiconductor exhibiting memristive behavior. In the microwave frequency range, the structure exhibits distinct transparency peaks/zones associated with its left-handed characteristics (double-negative, DNG-peaks/zones). The possibility of controlling these DNG transparency peaks/zones using static magnetic and electric fields is investigated. The findings highlight the potential of such metamaterials for the design and implementation of tunable components in microwave circuits.**

Keywords—planar metamaterial, left-handed medium, inverse split-ring resonator, memristor, microstrip transmission line

I. Introduction

It is well established that left-handed media (metamaterials/structures) are promising candidates for use in microwave-frequency circuit elements [1–7], owing to their fast-switching capabilities and relatively simple mechanisms for external control. Successful research in this field has been ongoing for over a decade. These structures are typically composed of alternating elements exhibiting metallic-like dielectric permittivity and magneto-resonant magnetic permeability. In the frequency range where the real parts of both constitutive parameters become negative, the structure can support wave propagation (i.e., become transparent), provided that the wavelength within the metamaterial significantly exceeds the characteristic size of its constituent elements [4–7].

Thus, a prototype of the fast-response [4–6], electrically and magnetically tunable passive microwave element is obtained. The primary obstacle to the practical application of such left-handed metamaterials in high-frequency technologies lies in the excessively large imaginary parts of the magnetic and dielectric permittivity of the constitutive parameters of natural materials that form them, which lead to significant electromagnetic energy losses. Consequently, key research directions in this field include: (a) the search for new low-loss natural materials, and (b) the optimization of the spatial configuration of such metamaterials.

In our recent study [4], we proposed a new type of left-handed metamaterial based on a nanostructured memristor. It was demonstrated that a bulk (3D) metamaterial composed of alternating ferrite elements and nanostructured TiO_2-based semiconductor (memristor) elements can exhibit left-handed properties in the microwave frequency range. Owing to the short relaxation times of the entire structure, such a metamaterial is a promising candidate for use as an electrically and magnetically tunable component of microwave band devices. The advantages of this new type of metamaterial stem primarily from the unique properties of TiO_2, which are manifested at nanometer sizes (on the order of 10^1 –10^4 nanometers [4]).

This paper presents further results in this research direction, specifically analyzing two structures based on the previously proposed model [4] but implemented in a more compact 2D geometry. This planar configuration reduces overall electromagnetic losses compared to the 3D case described in [4] and offers improved technological feasibility for device fabrication [10,11].

II. Structures Description

The structures investigated in this manuscript are as follows:

- Structure #1 (Fig.1, a), referred to as the "Strips Shaped Metamaterial," consists of a microstrip transmission line (shown in yellow color in Fig.1, a) placed on top of a dielectric substrate (shown in brown color in Fig.1, a) with metallization below. The permittivity of the substrate is $\varepsilon' = 2.2$. The width of the microstrip line is $a = 1.12$ mm. The structure #1 is bonded to the substrate on both sides, with the same thickness as the substrate ($d = 0.381$ mm), and is composed of alternating layers of ferrite and TiO_2. Structure #1 consists of 10 bi-elements. The width of each bi-element is $b = 15$ mm. The length of each ferrite element (shown in blue in the figure) is $c_f = 0.2$ mm, and the length of each TiO_2 element (shown in black in the figure) is $c_s = 50$ nm.

- Structure #2 (Fig.1, b), referred to as the "Ring-Shaped Metamaterial," is based on a microstrip transmission line and consists of several unit cells (in our case, 7). The microstrip line manufactured from TiO_2, with a width of $a = 1.12$ mm, is located on the top surface of a substrate with thickness $d = 0.381$ mm and permittivity $\varepsilon' = 2.2$. Periodically spaced linear gaps with a width of $\delta = 100$ mkm are etched into the microstrip line. Directly beneath these linear gaps, on the bottom surface of the substrate, ring-shaped gaps are formed

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

in a TiO_2 layer that coats the substrate. These ring-shaped gaps constitute Inverse Split-Ring Resonators (ISRRs) [8]. The ISRR parameters are radius $r = 3$ mm, ring width $s = 0.2$ mm, and center-to-center spacing between adjacent ISRRs $d = 0.5$ mm (the thickness of each TiO_2 layer equals 35mkm).

The electromagnetic wave propagates along the strip lines shown in the Fig. 1 for both structures, in the direction of the OY axis, from left to right.

III. Discussion

Fig. 2 (a, b) shows the transmission spectra obtained in the frequency ranges of 5–25 GHz for structure #1 and 1–10 GHz for structure #2. From these spectra, it is evident that in the frequency bands where the real parts of the permittivity of TiO_2 and the permeability of the ferrite are simultaneously negative, pronounced transmission peaks (transparency zones) are observed. These are indicated by vertical blue arrows in Fig. 2 (a, b), with the central resonance frequencies $f_{res}^{DNG} = 15.24$ GHz and 4.05 GHz respectively.

To clarify the nature of these peaks, spatial distributions of the electromagnetic field were simulated at the corresponding frequencies (Fig. 3, a, b). For each of the analyzed structures, the incident wave propagates from left to right. However, the spatial field profiles reveal the presence of a backward wave inside each structure, i.e., a wave (phase front) propagating from right to left.

Let us first analyze the spectrum of structure #1.

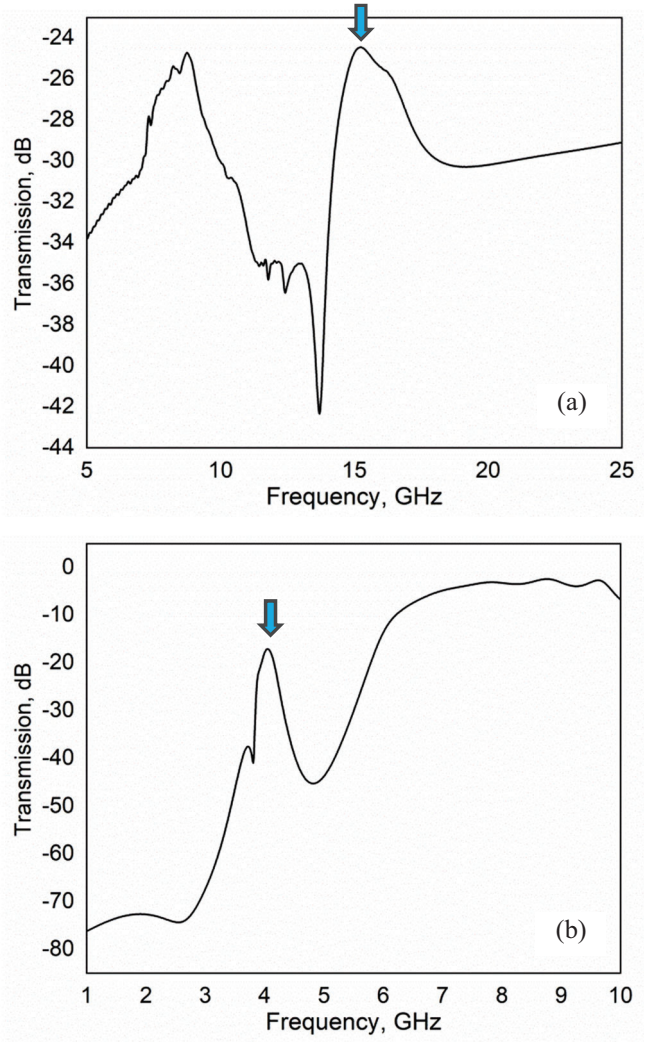

Fig. 2. (a, b) Transmission spectra corresponding to structures #1 and #2, respectively

The appearance of the transparency peak in the spectrum must be attributed to the fact that, at these frequencies, the real parts of both the dielectric permittivity and the magnetic permeability of the structure become simultaneously negative within the same frequency range, near the peak's resonance frequency 15.24 GHz. In detail, the method for calculating the frequency dependencies of these parameters for TiO_2 and ferrite separately, as well as for the entire composite left-handed structure, is presented in [4].

To investigate the effect of the gap width δ on the resonant frequency of the DNG peak in structure #2, the corresponding dependence was obtained and is presented in Fig. 4. The parameter δ was varied in the range of 100 to 700 μm.

For the cases analyzed in this work, our calculations confirm that the observed transparency peaks (like those in [4]) arise from the manifestation of left-handed properties in the studied structures. These peaks occur in a frequency range where the characteristic impedance of the left-handed medium approaches 1 and, therefore, are classified as Double Negative (DNG) zones/peaks. The physical origin of these peaks is associated with a specifically tailored phase

relationship between multiple reflected waves in the spatially periodic structure [1–7].

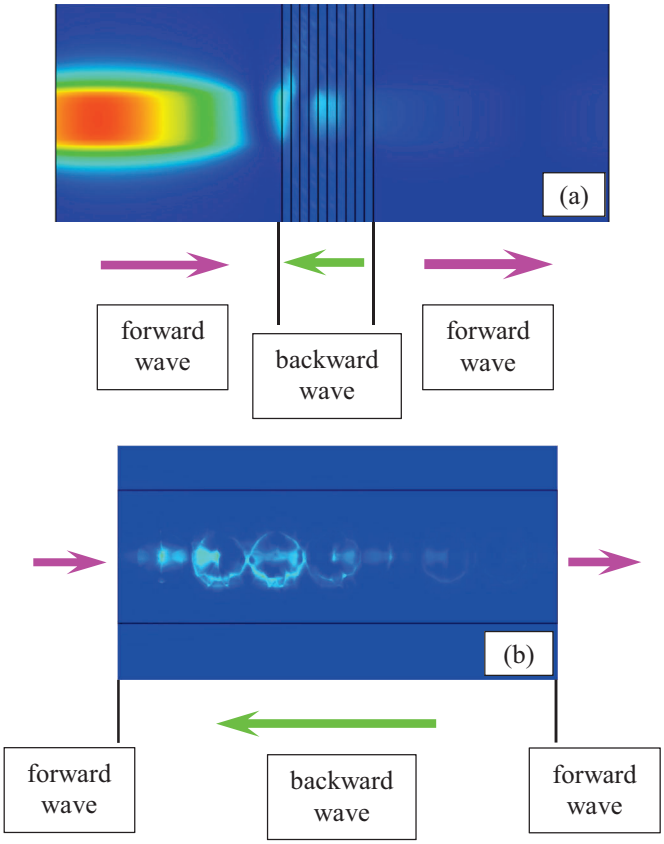

Fig. 3. (a, b) Spatial distributions of the electromagnetic field for structures #1 and #2, respectively

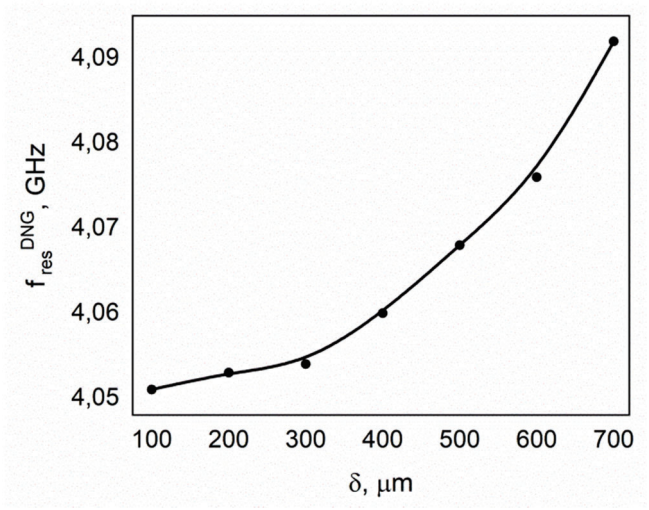

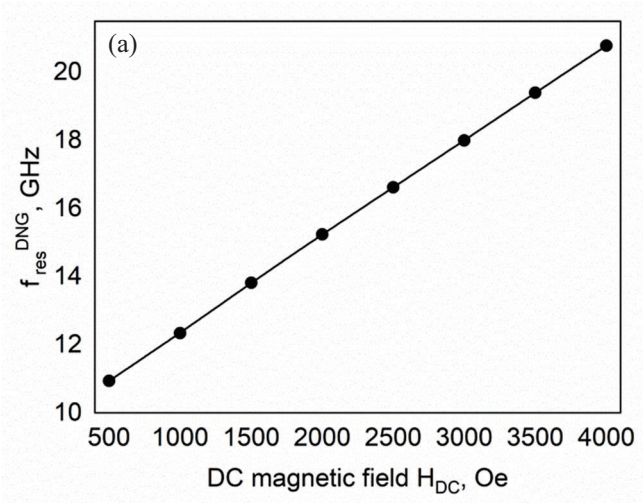

Fig. 4. Shift of the DNG peak as a function of gap width δ for stricture #2

Structure #2 may initially appear more technologically complex than structure #1; however, it offers several notable advantages. Most importantly, the fabrication (deposition) of the memristor elements is significantly simpler in structure #2 compared to structure #1. In the case of structure #1, each subsequent TiO_2 layer must be deposited on top of the previous one. Since the total number of layers can reach up to 10^2, and the deposition of each layer can take up to 1-2 days, the overall fabrication time for structure #1 becomes substantially longer than that for structure #2.

Structure #2 is based on the concept of a metamaterial previously discussed in [8]. In that paper, the negative effective permittivity of the metamaterial was achieved by incorporating varactor diodes into each ring-shaped element of the so-called split-ring resonator (SRR) [9], with the varactor acting as an electrically tunable component. In the present design, however, the entire TiO_2 memristor semiconductor layer assumes this role, making the resulting integrated system a more technologically advantageous solution. The negative effective permeability of the structure, meanwhile, is provided by its geometric configuration (the chain of rings) characteristic of traditional magnetic metamaterials.

Note that, as shown in [4], the electromagnetic properties of the studied structures (in particular, their DNG peaks) can be effectively tuned by both a static external magnetic field and a static external electric field. In particular, controlling metamaterial characteristics using a static magnetic field is a known and practically significant task [1–7]. Following the above-mentioned algorithm [4], we evaluated the shift in the resonance frequency (f_{res}^{DNG}) of the DNG peak (Fig. 5, a) as a function of the applied DC magnetic field H_{DC}.

The linear behavior of the resulting curve reflects the direct proportionality between f_{res}^{DNG} in accordance with motion equations [4,5].

Notably, structure #1 exhibits a substantial derivative value: $df_{res}^{DNG}/dH_{DC} = 2.96$ MHz/Oe . This value is approximately 20% higher than that reported in [4] for a considerably more technologically complex structure. This result highlights the potential of using a static magnetic field to achieve practical and efficient control of metamaterial properties.

We now analyze the possibility of tuning the DNG peak in structure #1 using a static electric field. As seen in Fig. 5, b, the dependence of the peak frequency on the applied electric field is nearly linear, similar to the behavior reported in [4]. This is attributed to the approximately linear

current-voltage (I–V) characteristic of the TiO_2-based memristor.

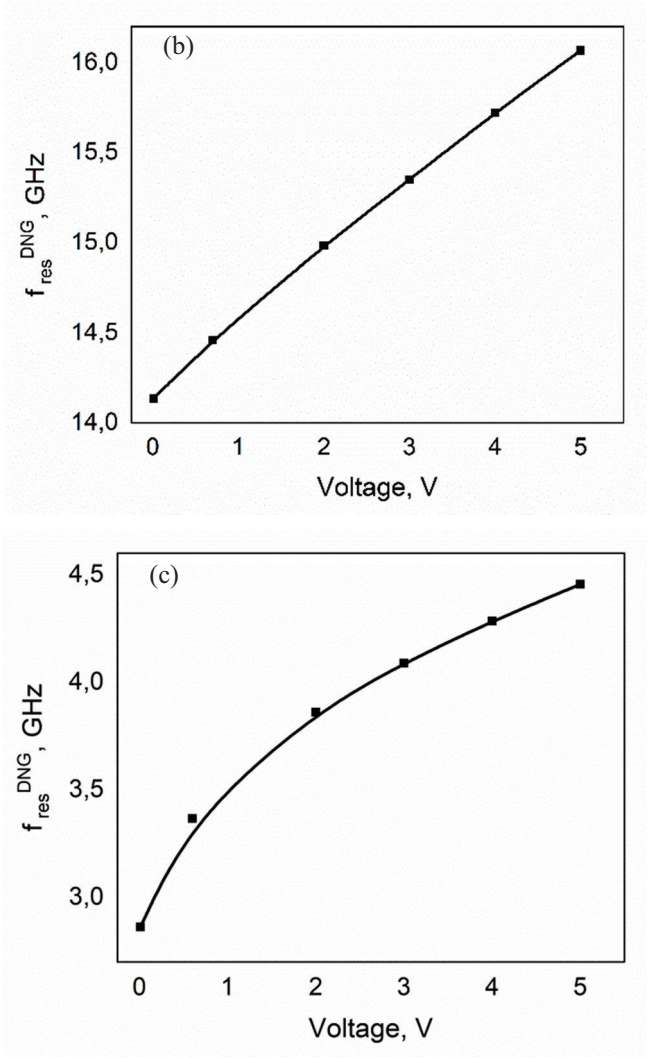

Fig. 5. DNG peaks behavior under external fields: (a) Variation of the DNG peak position with applied static magnetic field (H_{DC}) for structure #1; (b) Shift of the DNG peak as a function of applied static electric field / voltage (U_{DC}) for structure #1, H_{DC}=2000 Oe; (c) Shift of the DNG peak as a function of applied static electric field / voltage (U_{DC}) for structure #2

The derivative df_{res}^{DNG}/dU_{DC}, which characterizes the tuning efficiency of the resonance frequency, has a value comparable to that observed in the more technologically complex structure described in [4]: $df_{res}^{DNG}/dU_{DC} = 370$ MHz/V.

For structure #2, the dependence of the DNG peak frequency on the applied voltage is markedly nonlinear (Fig. 5, c). This behavior is due to the strongly nonlinear current–voltage characteristic of the TiO_2 memristor [4]. As a result, we observe in the higher voltage range $U_{DC} = (4-5)V$, the tuning rate is relatively moderate: $df_{res}^{DNG}/dU_{DC} \approx 170$ MHz/V. However, at lower voltages, in the range $U_{DC} = (0.01-1)$V, the derivative significantly increases: $df_{res}^{DNG}/dU_{DC} \approx 630$ MHz/V.

This analysis leads to the following conclusions:

IV. Conclisions

In summary:

1. The electrodynamic properties of a planar metamaterial based on a semiconductor nanostructure of the TiO_2 memristor type, as well as a composite structure formed by alternating planar (quasi-2D) ferrite and TiO_2 elements, have been numerically analyzed. It has been shown that in the microwave range, these structures exhibit transmission bands or peaks in the spectrum, caused by their left-handed characteristics.

2. The feasibility of precise tuning of the DNG peak frequency in the studied left-handed structures using both static magnetic and static electric fields has been demonstrated through numerical simulations.

3. A technological implementation of the proposed TiO_2 - ferrite nanostructured system has been suggested in the form of two configurations of promising electrically tunable components for microwave-frequency applications.

***Abstract*—The procedure of choice and application of complex sounding signals for ionospheric studies by the radar method of incoherent scatter (IS) of radio waves is considered. It is shown that the solution to the problem of reliable estimation of ionospheric parameters in an extended altitude interval with a sufficiently short time interval consists in improving the structure of sounding signals. It is proposed to modernize the process of pulse coding to obtain signals with specified correlation properties that make it possible calculating the ionospheric parameters both in the lower and upper parts of the ionosphere during a single measurement session. When synthesizing individual elements of the sounding signal, not only a change in the direction of circular rotation of the polarization plane of the radio wave is used, but also a change in the frequency of its radiation. For this purpose, the sounding signal should consist of groups of discrete-frequency elements representing radio pulses with different parameters. We propose to use an identifying neural network that enables estimating the parameters of ionospheric plasma in real time based on the obtained experimental autocorrelation functions of the IS signal.**

Keywords—incoherent scatter method, signals and sounding modes, coding of radio pulses, neural network signal processing

I. Introduction

Advances in understanding the physical processes in near-Earth space have been achieved through the use of new research methods, among which the incoherent scatter (IS) method occupies a special place. A detailed review of the theoretical aspects and practical use of this method, as well as the types and features of radars designed for these purposes, is presented in numerous publications.

Using the IS method, it became possible to determine simultaneously a number of ionospheric parameters, such as electron density, electron and ion temperatures, ion composition, plasma drift velocity, and many others. It is with the use of this method that the IS radars, created by Kharkiv polytechnic scientists, operate with a unique 100-meter (in diameter) fixed zenith antenna and a fully steerable 25-meter antenna [1, 2]. The results obtained with their use for more than half a century have been of great fundamental and applied importance for world science. For example, information on the state and dynamics of ionospheric plasma is extremely necessary both from the point of view of deepening knowledge about near-Earth space and for solving many practical problems in industries covering the activities of space weather systems, satellite communication systems, and object positioning systems in space, which indicates the relevance of obtaining this information at the present stage.

Traditional radar uses sounding signals that enable determining the coordinates and speed of objects that are point targets in outer space and airspace, on the surface of the earth and the water surface [3–6]. In the case of measurements using the IS method, the ionospheric plasma is a spatially distributed target, and the requirements for the type of sounding signal are significantly more complex than in traditional radiolocation. Therefore, a number of foreign authors proposed different signal options and sounding modes [7–9], which were subsequently improved by our Ukrainian scientists [10, 11].

In the sequel, the process of choice and using complex signals for studying geospace was continued. It was emphasized that in the process of synthesizing optimal signals for ionospheric sounding, radar equipment, sounding modes and processors for IS signal processing should be considered as interconnected elements of the system. Accordingly, the objective of the presented studies is to improve the sounding process and subsequent radar processing of the IS signal to study the state and dynamics of the ionosphere in an extended altitude interval with sufficient range (height when vertical sounding) resolution. Since the main carrier of information on the state of the ionospheric plasma are the experimentally obtained statistical characteristics of the scattered signal (in particular, the autocorrelation function (ACF)), we consider the case of a more accurate determination of these characteristics by using elements of the complex sounding radio signal coded by several parameters.

II. Analysis of the Pulse Signal Sounding Mode

Since the ionospheric plasma has a structure that changes with altitude, it is proposed to use different modes in the process of conducting experiments to determine its characteristics. The implementation of such modes with a gradual complication of probing signals began more than 50 years ago [12–14]. Recently, similar approaches have been proposed for studying the ionosphere at altitudes <400 km, where its parameters change significantly with altitude. In this case, the modes of radiation of multi-element pulsed sounding signals (Fig. 1, a) are used, making it possible to obtain the ordinates of the normalized ACF of the scattered signal with high resolution both in altitude (Δh) and in correlation delay ($\Delta\tau$). This is achieved

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

by using manipulation of the direction of circular rotation of the polarization plane of the radio wave during its radiation. However, these pulses enable to obtain only the right-hand side of ACF, i.e., in the interval of correlation delay from τ_1 to τ_2 (Fig. 1, c).

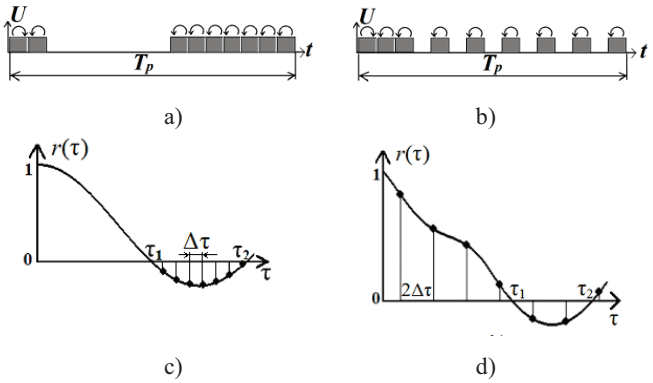

Fig. 1. Envelopes of pulse elements of the sounding signals (a, b) and the normalized ACFs of the scattered signal obtained with their help for two sounding modes (c, d). The arrows conventionally indicate the direction of circular polarization of each emitted pulse element.

For the study of the upper altitude range of the ionosphere, an algorithm for searching for the structure of the sounding signal was developed and a new arrangement of elements in the sounding pulse was obtained [15, 16] (Fig. 1, b). This option also enables obtaining the ACF ordinates with a high resolution along the height. However, since the spectrum of the scattered signal expands with increasing height due to the presence of light ions in the upper ionosphere, and the ACF acquires a complex shape, it is necessary that the ACF ordinates be obtained in the delay interval from 0 to τ_2 (Fig. 1, d). With the same total duration of the sounding pulse, this option for the arrangement of the coded elements provides a 2-fold worse resolution in correlation delay: $2\Delta\tau$.

Below, we propose such a variant in the algorithm for searching for combinations of coded elements of the probing signal, in order to simultaneously (in one measurement session) implement both of these modes for determining the ordinates of the ACF of the IS signal while ensuring the maximum acceptable resolution both in height and in correlation delay for the simultaneous study of the lower and upper altitude ranges of the ionosphere.

III. Improving the Structure of the Sounding Signal

The results of calculations using a computer program of a number of combinations of coded elements in the structure of a sounding signal with total duration T_p are given in [16]. The main rule in their search was that the most active element should be located at the beginning of the coded pulsing.

In the process of calculating the ordinates of the IS signal ACF, the echo signal from this element is involved in multiplication with the echo signals from all subsequent elements shifted relative to the first element by $\tau_k = k\Delta\tau$ (k is the number of the correlation delay). The results of the multiplications for each altitude section with a length of $\Delta h = c\tau_{el}/2$ and a center at height $h_0 = ct_0/2$, which this first element has reached, are statistically accumulated in the working memory. Here c is the speed of light, τ_{el} is the duration of the pulse element of the sounding signal.

The signals proposed in [15, 16] enable using only 8 elements as active ones for calculating up to 7 ACF ordinates (Fig. 1, a, b), while the total duration of the signal allows containing up to 15 elements. In addition, it is necessary to use two coded sequences in turn, corresponding to the process of studying the lower or upper altitude range.

We proposed to modernize the process of synthesis of coded elements of the sounding pulse signal, namely:

– to fill completely the pulse with active elements, for example, with different carrier frequencies (ensuring that the spectra of the scattering signals caused by them do not overlap) and with different directions of circular polarization of the emitted wave;

– thereby ensure the optimal operating mode of the radar transmitters;

– have the ability to determine the ACF ordinates in each radar scan with satisfactory accuracy when receiving scattered signals simultaneously from the lower and upper altitude ranges.

The results of the synthesis of multi-element coded signals that satisfy these requirements are presented in Fig. 2 as one of the fragments. The black elements are supposed to be emitted at the frequency f_1, and the gray ones at the frequency f_2.

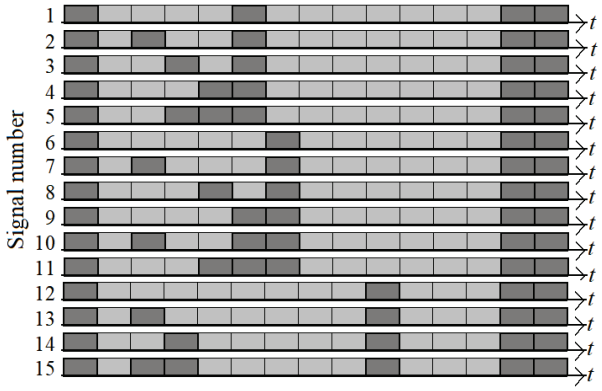

Fig. 2. Results of the search for multi-element coded signals that provide simultaneous calculation of up to 13 ordinates of the scattered signal ACF.

Table 1 illustrates the analysis of the capabilities of these signals.

TABLE I. Information on the Calculation of ACF Ordinates.

Signal number (according to Fig. 2)	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**	**13**	**14**	**15**
Total number of multiplications	7	12	11	7	9	7	12	11	7	13	9	7	12	11	15
Number of ACF ordinates obtained	7	11	10	7	8	7	11	11	7	12	9	7	11	10	13

The first line is the numbers of the found signal variants, starting from the top one in Fig. 2. The second line is the total number of mutual multiplications between elements within the implemented signal. The third line is

the number of ACF ordinates that can be obtained with these multiplications.

For greater clarity, the information on this table is presented graphically in Fig. 3, a. When comparing these 15 versions of sounding signals, one can observe different cases of the location of the calculated ACF ordinates along the axis of correlation delays. Larger dots indicate better calculation statistics (these ordinates were obtained twice).

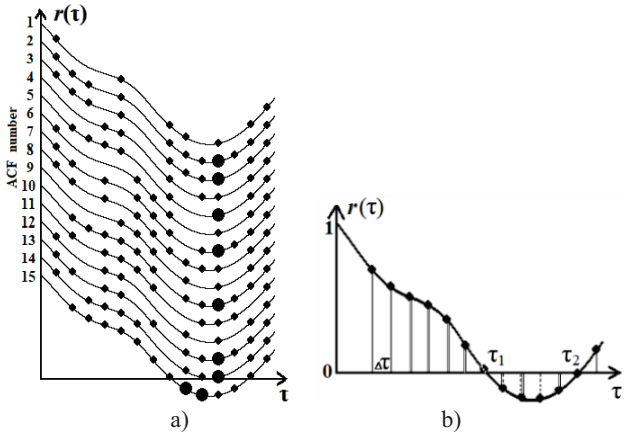

Fig. 3. Versions of the location of the ordinates of the scattered signal ACF (a) when using the sounding signals shown in Fig. 2, and the lower (15th) version (b) as the the optimal one.

Based on the information presented, coded signal number 15 is proposed for subsequent use (see Fig. 2). It makes it possible to obtain a sufficient number of uniformly distributed ACF ordinates (Fig. 3, b), and the small step of their location along the correlation delay axis satisfies the requirements for calculating ionospheric parameters from the shape of the ACF of signals scattered by plasma in both the lower and upper altitude ranges.

Thus, as a result of such a choice of the arrangement of the coded elements of the sounding signal, it will look in its final form upon emission as shown in Fig. 4.

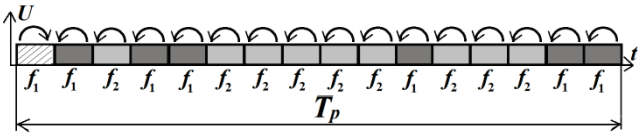

Fig. 4. Envelopes of coded elements of the sounding pulse.

The first element of the sounding signal will have a right-hand direction of rotation of the plane of polarization of the radio wave, as in [16], which will make it possible to obtain the power of the IS signal in a separate receiving channel for subsequent normalization of the ACF ordinates. All other elements intended for calculating the correlation coefficients will have a left-hand direction of rotation. The duration of each code element $\tau_{el} = 30$ μs that we have chosen provides a quite acceptable altitude resolution $\Delta h = c\tau_{el}/2 \approx 4.5$ km with a total length of the sounding pulse $T_p = 30 \times 16 = 480$ μs [17, 18].

The process of propagation in space of the elements of the coded pulse separately at frequencies f_1 and f_2 is shown in Fig. 5 and Fig. 6. The figures demonstrate the possibility of obtaining the ACF ordinates by multiplying not only the echo signal from the first element of the pulse by the echo signals from the rest of elements, but also by additional mutual multiplications between the echo signals from these rest code elements.

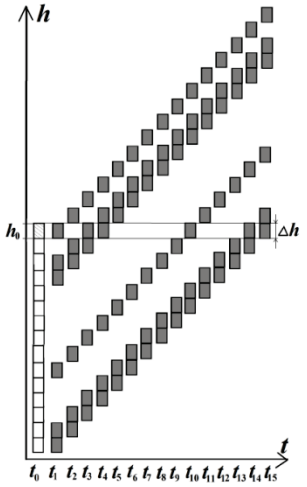

Fig. 5. Process of propagation in space of the coded pulse elements at frequency f_1.

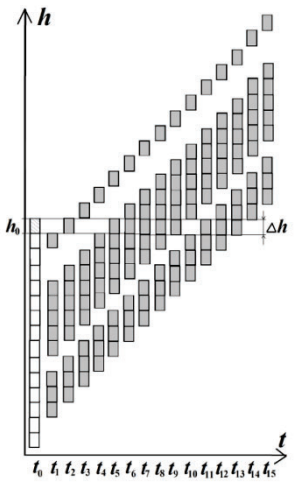

Fig. 6. Process of propagation in space of the coded pulse elements at frequencies f_1 and f_2.

In the final form, the obtained ordinates of the normalized ACF of the scattered signal will look like in Fig. 3, b. Single vertical lines on the graph mean that these ordinates (numbers 2, 3, 9, 13, and 14) will be obtained at frequency f_1 using multiplications of the echo signals from the first element with those from the other pulse elements. Ordinates numbered 4, 5, 6, 7, 10, and 12 (double lines) will be obtained at the same frequency, but using mutual multiplication of echo signals from pulse elements without involving the first element. Ordinates numbered 8, 9, 10, and 11 (dashed lines) will be obtained at frequency f_2.

The calculation of the ACF ordinates is performed in specialized devices – correlators, the structure of which depends on the processing option [16, 19].

IV. Network Technologies in the Incoherent Scatter Method

The calculation procedure in the IS method consists of calculating the parameters of the ionospheric plasma using the experimentally obtained ACF of the scattered signal. The peculiarity is that due to the absence of direct analytical formulas, this calculation is based on the iterative procedure of solving the inverse problem. Its essence lies in comparing each ACF obtained at each studied altitude section with a set of theoretical analogues, previously calculated according to physical concepts of the nature of the ionospheric plasma. These analogues are stored in the computer memory (N model correlation functions with K ordinates in each of them). When using them alternately with the use of the coordinate descent method and the concomitant use of the convolution operation (to take into account the current characteristics of the ACF of the filter of the receiving system of the IS radar), the surface of the residual function is formed. This is a rather slow calculation procedure, and the most time-consuming operations are operations of matrix multiplication (convolution). Therefore, the goal of further improving this procedure for real-time operation is to increase its speed by parallelizing the ACF identification process using theoretical analogs.

A significant number of publications are devoted to solving such problems, and among them the principle of using artificial neural networks is of interest. Interesting results are given in the studies of T. Kohonen [20] on the example of self-organizing structures used in recognizing images represented by vector quantities. In addition, in [21], there is a description of a significant number of features that the problem being solved must have so that the use of convolutional neural networks to be justified. The main ones, taking into account our conditions, include the following:

– there is no strict mathematical expression, but a sufficient amount of experimental data has been accumulated;

– the processing process is characterized by large volumes of information;

– data received under ionospheric interference conditions are significantly noisy.

As we can see, according to these features, neural networks can be used to recognize the ACF shapes of the IS signal, during which the parameters of the ionospheric environment are assessed using correlation functions.

Let us formulate the tasks of statistical processing of ionospheric information as follows. It is necessary to determine the unknown parameter θ, characterizing the state of the ionospheric plasma, having information about the K ordinates of the experimental ACF $r^{\mathrm{e}}(k; \boldsymbol{\theta})$, which are obtained during the processing of the scattering signal. This approach involves the algorithm of functioning of associative memory and can be organized using a neural network. In our case, there is a certain set of reference, theoretical correlation functions, among which the network should be able to select the reference sample, most similar to the ACF obtained in the experiment.

To implement this network, we will define the algorithm of its functioning for our case. It should correspond to the calculation of the elements of the residual function when solving the difference functional of the following type:

$$\chi_n^2(\boldsymbol{\theta}) = \sum_{k=2}^{14} \left[r^{\mathrm{e}}(k; \boldsymbol{\theta}) - \langle r_n^{\mathrm{t}}(k; \boldsymbol{\theta}) \otimes r^{\mathrm{f}}(k) \rangle \right]^2.$$

Here the symbol ‹⊗› denotes the operation of convolution of each of the $n = 1 \ldots N$ theoretical ACFs of the signal $r^{t}(k)$ with the ordinates of the filter ACF $r^{f}(k)$. This operation is intended to take into account the influence of the receiver filter, as the narrowest-band element of the receiving path, on the measured characteristics of the useful IS signal. It simulates the distortion of the theoretical ACF of the ionized medium as a result of the passage of the conditional signal through the receiver filter, similar to what actually occurs with the experimental ACF of the IS signal.

As a result, the identifying neural network (Fig. 7) should have several layers of neurons in the proposed radial-basis structure. Since the IS radar of Institute of Ionosphere of NTU "KhPI" currently uses a library of N = several thousand theoretical ACFs, and in accordance with this experiment, ACFs with K=13 ordinates each will be obtained, then in such a structure, the neurons of the input layer $\mathbf{A^1}$ should be organized in the form of a continuous delay line with a length of 13N cells. These cells are intended for filling them with the values of the ordinates of the theoretical ACFs, i.e., at the beginning of processing, the network perceives service information about r^{t}, after which it is ready for work.

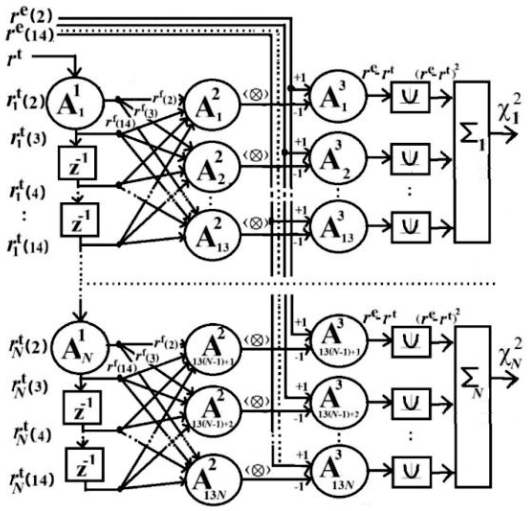

Fig. 7. Identifying neural network for ACF recognition of the HP signal.

Subsequently, the information is transmitted through the neurons of the interface layer that represents by elements of the synaptic connections $r^{\mathrm{f}}(k)$ and enables the implementation of the process of convolution of two functions.

Layer $\mathbf{A^2}$, in which the results of the convolution are accumulated, passes them to layer $\mathbf{A^3}$, which has the form of difference neurons with connections at the input of the form "±1" to determine the difference between the values of the ordinates being compared. Quadratic activation functions are at the outputs of this layer. The summation of the squared results of calculating the differences occurs in the last interface layer ∑, i.e., at its outputs, we have all n = 1, 2, …, N elements of the χ^2 residual function.

Thus, the neural network relates the input value $r^{\mathrm{e}}(k; \boldsymbol{\theta})$ simultaneously to the entire set of N updated (taking into account the filter) theoretical analogues. The value $\chi^2_{\min}$, which the computer finds among the list of obtained values of the residual function, reflects the degree of best proximity and corresponds to the sought ACF $r^{\mathrm{t}}(k; \boldsymbol{\theta})$ and the vector θ of ionospheric parameters.

Such a neural network makes it possible implementing simultaneous identification of the obtained ACFs r^{e}, using all the involved theoretical analogs r^{t}. The network is trained using the procedure of reconfiguring the weights $r^{\mathrm{f}}(k)$ to implement new current experimental conditions using test reference (noise-free) values of r^{e}. That is, in the case of using another type of filter in the receiving system of the IS radar, the neural network learns by adjusting to the new weights $r^{\mathrm{f}}(k)$ until zero results are obtained at the corresponding outputs χ^2. In addition, it is possible to use special methods for signal processing that increase the efficiency of processing by reducing computational costs and increasing the speed of algorithms, for example, [22].

When performing this work, the task was set to programmatically model a network with a simplified

architecture (only for several theoretical functions r^t). As a result, this modeling confirmed the efficiency of recognizing various forms of the scattering signal ACF, i.e. the operability of the proposed identifying neural network. In the future, the hardware implementation of this neural network is considered, taking into account specialized neuroboards. Similar products based on the use of the mechanism of action of neural networks have begun to appear on the market. For example, the large-scale integrated circuit developed by Adaptive Solutions (USA) contains 64 neurons, has 262144 synaptic connections and allows a speed of up to 1.2 billion connections/sec [23]. These elements will certainly become the basis for specialized multiprocessor devices, including those for the IS method.

V. Conclusions

The procedure for choice of complex sounding signals for studying the ionosphere using the incoherent scatter method is considered in order to improve the sounding process and subsequent radar processing of the IS signal to determine the state and dynamics of the ionosphere in an extended altitude range with sufficient resolution in range (altitude when vertical sounding) and time.

It is proposed to modernize the process of coding of these signals. When synthesizing individual elements of the sounding signal, it is proposed to use both the change in the direction of the circular polarization of the radio wave and the manipulation of the carrier frequency. The results of searching for this type of multi-element coded signals are presented.

To identify the correspondence of the obtained experimental ACFs of the scattered signal to their theoretical analogs, it is proposed to use an identifying neural network that allows for operational real-time assessment of the ionospheric plasma parameters. This network is the basis for the future creation of flexible and high-speed ionospheric information processing systems.

This work performed contributes to the development of means for monitoring the near-Earth environment, which has a significant impact on many terrestrial processes and on the state of which the quality of functioning of modern communication, radar and radio positioning systems depends.

Abstract— **The objective function for filament defect detection utilizes thermal quadrupoles in a cascading configuration to model a multi-layer structure with a defect. The model combines matrix products representing each layer. Two approaches for thermal quadrupole models are considered. The first approach simplifies the defect model to a thermal resistance layer, providing analytical expressions for defect thickness and depth, which offers some advantages but may lead to complexities due to the non-symmetric defect matrix. The second approach, focusing on a symmetric defect layer matrix, is more mathematically sound and has greater informational value, making it more suitable for this study. Initially, hyperbolic functions were used for modeling heat transfer, but due to their complexity, trigonometric functions were adopted for practical implementation. The objective function, which aims to identify defect parameters, incorporates these models and could eventually be integrated into a larger defect detection algorithm. This would automate the defect-checking process, enhancing practical applications. Simulation results incorporate sensor imperfections using random error (1%) in the equations, adding realism to the model without introducing significant distortions. These errors are minor and unlikely to affect practical applications given the expected thickness of the filament.**

Keywords—thermal quadrupoles, model, defect, multilayer, dielectric, objective function

I. INTRODUCTION

The thermal quadrupole method is a mathematical approach based on electrothermal analogies and the fundamental heat conduction equation. Initially introduced by H.S. Carslaw, and later developed further with J.C. Jaeger, the method uses Laplace transforms to solve complex thermal problems, particularly in systems with periodic or transient heat flow [1,2]. Its modular nature makes it well-suited for analyzing multilayered materials and structures, allowing each layer to be modeled as an individual quadrupole and combined in a cascade matrix configuration [14].

For precise thermal modeling, accurate thermal property measurements are essential. Reference [3] presents a comprehensive guide to selecting and applying suitable thermal measurement techniques, offering practical insights for both experts and non-specialists. This foundation is especially relevant in cases where thermal models are used for material characterization and defect detection.

In the context of 3D printing, defectoscopy focuses on identifying imperfections in printed filament structures. Since many filament parameters (e.g., thermal conductivity, density) are known a priori, thermal models can be adapted efficiently. Research in this area includes the use of terahertz time-domain spectroscopy (THz-TDS) to determine refractive indices while correcting for internal reflections [12]. The thermal quadrupole method has also been adapted to improve modeling accuracy for multilayer filament structures and to detect defects located between layers [14,15].

Several studies [4,5] have demonstrated the effectiveness of pulse thermography (PT) and transient thermal imaging in identifying delamination in multi-layered composite materials. These methods are particularly efficient when combined with analytical tools such as locally normalized thermal contrast and Laplace-transformed data, enabling the reconstruction of contact resistance and defect depth profiles. Results have shown strong correlation with traditional ultrasonic methods, indicating their reliability and speed for non-destructive testing (NDT) [4].

For an NDT technique to be effective, the simulated defects must realistically represent actual flaws in shape and material properties. One such study examined debonding at the edge of a composite patch using polyurethane, providing insights into accurate experimental setup and improving understanding of heat transfer behavior at critical bonding interfaces [6,7].

Thermal behavior in laminated structures can be significantly influenced by mechanical loading and defect geometry. Numerical models that simulate heat transfer under these conditions help predict temperature contours and identify delamination effects, considering parameters like shallow depth and thermal resistance [8].

Thermal quadrupole modeling has proven effective in designing and optimizing thermographic inspections. Parametric studies using two- and four-layer models demonstrate the method's adaptability to various composite systems, contributing to better planning of inspection protocols [9].

Passive thermography offers real-time, in-situ monitoring capabilities, especially useful during cyclic mechanical loading of composite materials. Modeling of subsurface heat generation enables accurate prediction of surface temperature changes, aiding in early defect detection [10].

An important development is the creation of analytical models that relate defect characteristics (e.g., opening, depth, temperature, conductivity) to the resulting thermal response under controlled heating. Such models enhance the interpretability of thermographic data and support the use of active thermal control strategies [13].

Across all studies, thermographic NDE methods – including both active and passive approaches – are

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

emphasized as critical tools for high-reliability sectors like aerospace, where early detection of internal defects can prevent structural failure [11].

The reviewed works collectively highlight the effectiveness and adaptability of thermal quadrupole modeling and thermographic methods in the non-destructive evaluation of composite and 3D-printed materials. From fundamental heat conduction theory to advanced layered simulations, these approaches support accurate, fast, and reliable detection of internal defects such as delamination, debonding, and voids. By integrating analytical modeling, experimental thermography, and real-time monitoring techniques, these methods provide a comprehensive toolkit for ensuring structural integrity in modern engineering materials.

The purpose of the work is to improve the model in the form of thermal quadrupoles for multilayer dielectrics, namely for non-destructive defect detection of filament for 3D printing, which has internal defects. The improvement is carried out by finding additional connections between opening, depth, temperature, and thermal conductivity.

II. Multilayer Model with Inner Defects

A. Thermal Conduction Equation

As a thermophysical model of the sample, we will consider a multilayer unlimited plate of thickness l, one of the layers of which, differing in thermophysical characteristics, is a defect(Fig.1). Fig. 1 shows a multilayer sample, where λ, λ_d are thermal conductivity of the material of the sample and the defect, W/K m^2, a, a_d are thermal diffusivity the material of the sample and the defect, m^2/s, h is the depth of the defect, mm, δ is opening of the defect, mm, lower index d is defect.

The direct problem involves determining the heat flux at the output and the temperature if the input values for temperature and heat flux are known. The inverse problem entails identifying the defect parameters by analyzing the temperature and heat flux at both the input and output of the sample. A significant challenge in this research is the difficulty of measuring temperature and heat flux between layers without causing damage, which complicates non-destructive testing. The main problem of the study is the inaccessibility of the places between the layers for measuring the temperature and heat flux, as it should be during non-destructive testing.

The mathematical model includes the equation of non-stationary heat conductivity of the form

$$a\frac{\partial^2 T(x,\tau)}{\partial x^2}=\frac{\partial T(x,\tau)}{\partial \tau}, \tag{1}$$

where T is temperature, x is coordinate (fig.1), τ is time.

The generally accepted boundary conditions are

$$T\big|_{\tau=0}=0;\ T_{x=0}=T_1;\ -\lambda_1\frac{\partial T}{\partial x}\bigg|_{x=0}=Q_1(\tau); \tag{2}$$

$$-\lambda_n\frac{\partial T}{\partial x}\bigg|_{x=l}=Q_n(\tau);\ \ Q_1=q_1-\alpha_1 T_1;\ Q_n=-q_n+\alpha_n T_n. \tag{3}$$

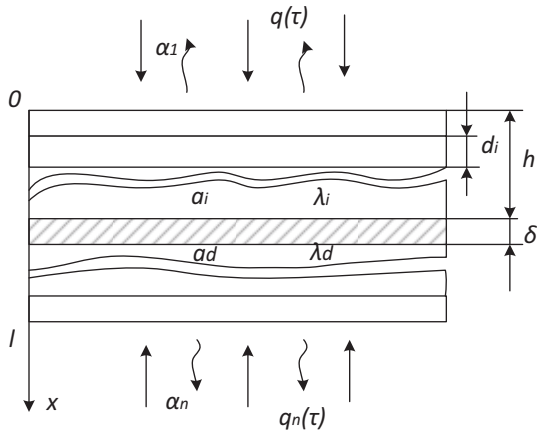

Fig.1 Multi-layer sample

To determine temperature as a solution to the heat conduction equation with specified boundary conditions, the result is expressed as a sum of trigonometric functions within a rectangular coordinate system. The heat flow is directly related to temperature through its derivative, which translates into heat flux with an associated coefficient. When obtaining this derivative, the trigonometric functions are differentiated according to standard rules, where sine and cosine functions are interchanged with corresponding sign.

B. Thermal Quadrupoles Model as Development of Thermo Conductivity Equation

The method of thermal quadrupoles is most descriptive when dealing with Laplace transforms of surface (F-front and R-rear) temperatures and heat fluxes:ΘF, ΘR, ΦF, ΦR [4].

The problem is solved in the matrix form

$$\begin{bmatrix}\theta^F\\ W\end{bmatrix}=M_1M_dM_3\begin{bmatrix}\theta^R\\ 0\end{bmatrix}, \tag{1}$$

where $\theta^F(z,p)$, $\theta^R(z,p)$ are the Laplace transforms on the front and rear surfaces, M1,M2 are the matrices characterizing plate layers (except the defect)

$$M=\begin{vmatrix}A & B\\ E & D\end{vmatrix}, \tag{2}$$

where

$$A=D=\cos h(kl);\ E=\lambda k\sinh(kl);$$
$$B=\sinh(kl)l(\lambda k);\ k=\sqrt{p/a}. \tag{3}$$

Respectively, for the matrix Md describing the defect layer

$$A_d=D_d=1;B_d=R_d;\ E_d=0. \tag{4}$$

In the Laplace domain, the front and rear-surface solutions are algebraic, thus allowing the calculation of defect depth l1 and thermal resistance Rd = d/λd.

III. Objective Function for Filament Defect Checking

Thermal quadrupoles can be cascaded to model the multi-layer structure of a sample with a defect, with each layer represented by the product of its corresponding matrix. Two approaches to thermal quadrupole models are explored in the literature ([2-4] and [13]).

The first approach, as seen in [2-4], simplifies the defect model to a thermal resistance layer, making the expressions for defect thickness and depth analytical, which is advantageous. However, this simplification can introduce complexities, particularly due to the non-symmetric nature of the defect matrix.

In contrast, the second approach, outlined in [13], uses a trigonometric identity ($\cos^2\theta + \sin^2\theta = 1$) to express the defect layer thickness. While this approach is mathematically robust, it lacks the depth of informational value found in the first model. However, the second model offers the benefit of a symmetric thermal quadrupole matrix, which is preferable to the non-symmetric model from [2-4].

The symmetric defect layer matrix approach is more appropriate for our research, and it was the model chosen for implementation. Initially, hyperbolic functions were considered, as they are theoretically better suited for modeling heat transfer in dielectric materials with defects. However, their complexity made them less practical for real-world applications. Trigonometric functions, by comparison, are simpler and easier to implement. Therefore, for the time being, the model will utilize trigonometric functions, with the potential to transition to hyperbolic functions in the future, pending successful model validation and error analysis.

For a multilayer filament (see Fig. 1) objective function is

$$\begin{aligned} F_1 &= (t_1 - \cos(kd + kh + k_d\delta))^2 + \\ &+ \left(t_2 + \sin(kd + kh + k_d\delta)\right)^2 + \\ &+ (t_3 - \cos(kd + kh + k_d\delta)^2 + \\ &+ \left(t_4 - \sin\left(kd + kh + k_d\delta\right)\right)^2, \end{aligned} \tag{5}$$

$$\begin{aligned} &\frac{\partial F_1}{\partial\left(k_d\delta\right)} = 2t_2\cos(kd + kh + k_d\delta) - \\ &-2t_4\cos\left(kd + kh + k_d\delta\right) + \\ &+2t_1\sin(kd + kh + k_d\delta) + \\ &+2t_3\sin\left(kd + kh + k_d\delta\right) = 0, \end{aligned} \tag{6}$$

where t_i defined experimentally, it is constant for each measurement case. From (6) sues

$$tg\left(kd + kh + k_d\delta\right) = \frac{t_2 - t_4}{t_1 + t_3}. \tag{7}$$

$$kd + kh + k_d\delta = arctg\left(\frac{t_2 - t_4}{t_1 + t_3}\right). \tag{8}$$

The thickness of a multilayer sample without defects is obtained through measurement. The value of k is calculated for known materials, such as a specific filament, based on reference data.

$$kl = k(kd + kh + k\delta), \tag{9}$$

If expression (9) result is not equal $arctg\left(\frac{t_2 - t_4}{t_1 + t_3}\right)$ This means there is a defect in the sample.

The objective function (which represents the goal of identifying defect parameters) could eventually be woven into a larger algorithm. This will allow for the automation of defect detection, making it easier to apply the model in practical scenarios.

While the model's theoretical framework has room for refinement, the current approach has potential, especially as we move toward integrating more advanced functions and improving error handling in future iterations

IV. Simulation and Uncertainty Definition

For the modeling process, we will incorporate the imperfections of the sensors by adding the rnd function to the equations that describe the layers. Errors have been introduced into the model using the MathCad rnd function, with a 1% random error (i.e., rnd(0.01)). This ensures that the model accounts for real-world imperfections in measurements, though these errors are kept within a reasonable range to avoid significant distortions in the results.

The relative error is calculated using the following formula

$$\Delta = \frac{\frac{t2(kd, kh, k_d\delta) - t4(kd, kh, k_d\delta)}{t1(kd, kh, k_d\delta) - t3(kd, kh, k_d\delta)} - \left(kd + kh + k_d\delta\right)}{kd + kh + k_d\delta}, \tag{10}$$

The dependence of total sample thicknes from first layer thickness is shown on the fig.2.

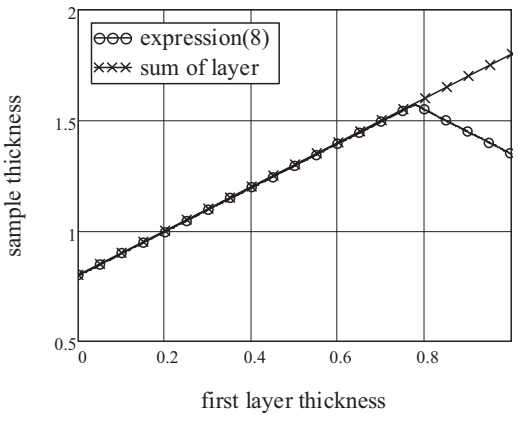

Fig.2 Dependence total sample thicknes from first layer thickness

After reaching 0.6 of the normalized layer thickness, the expression starts to exhibit an error. However, up until this point, it behaves correctly and aligns with the physical expectations of the problem. Since the filament is relatively thin, it is unlikely that we will encounter this part of the graph in practice.

Fig. 3 illustrate the behavior of the relative error fromexpression (10).

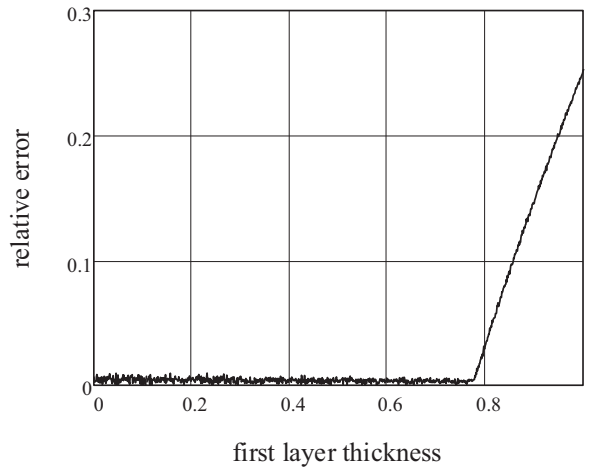

Fig.3 Dependence of relative errore from defect location depth

V. CONCLUSION

This study presents a thermal quadrupole model for detecting defects in multi-layer filament structures, highlighting the advantages and trade-offs of two approaches for modeling the defect layer. The first approach simplifies the defect to a thermal resistance layer, offering analytical expressions for defect thickness and depth, but introduces complexities due to non-symmetric matrices. The second, more suitable approach utilizes a symmetric defect layer matrix, providing greater mathematical clarity and informational value.

While the model initially used hyperbolic functions for heat transfer, it was found that trigonometric functions offer a simpler and more practical implementation for defect detection in real-world applications. The objective function developed in this study serves as the foundation for identifying defect parameters and can be integrated into a broader defect detection algorithm, which would enable automated analysis and improve practical usability.

Simulations incorporating sensor imperfections demonstrate that the model accurately reflects the behavior of the system under realistic conditions, with minimal error introduced by random measurement uncertainties.

Future work may involve refining the model further, potentially transitioning to hyperbolic functions for greater precision once the feasibility and error margins are thoroughly evaluated. Overall, the current approach holds promising potential for effective and efficient defect detection in filament materials

***Abstract* − Ensuring the comfort and safety of passengers is one of the most important tasks in the design and maintenance of passenger rail transport. One of the threats to passenger comfort and safety arising from train movement is its oscillations, which are mainly caused by irregularities of the railway track. The paper proposes the use of Statistics-Informed Neural Network (SINN) for track irregularity modelling due to its ability to reproduce stochastic processes according to their statistical characteristics. In this work, a computer program was developed to generate short-time track profile trajectories based on track irregularity power spectrum. The obtained short-time trajectories were used as a target sample for training a neural network. The trained neural network generates samples of railway track irregularities that are close to real ones and have the same statistical characteristics. The obtained neural network is able to generate trajectories of railway track irregularities that are longer than the training samples, while maintaining the features of the desired stochastic process. It can be used to model irregularities on sections of track of various length and further used in a complex model of vertical oscillations of rolling stock for the on-board control systems of Ukrainian trains.**

Keywords: rolling stock, oscillatory process, track irregularities, neural network, SINN, decision support system, on-board control systems.

I. Problem Statement

Ensuring the comfort and safety of passengers is an important task that scientists are working on both at the design stage of rolling stock and during the repair and maintenance of existing trains. One of the threats that arise when a train is moving along a railway track is the forced oscillations of the carriage and its components. They lead to accelerated wear of the suspension system, contact surfaces of wheels and a track, cause loss of wheel grip and, ultimately, increase energy consumption. Critical values of accelerations in the vertical and transverse planes can also lead to passenger discomfort and even train derailments [1−3]. The negative effects of car oscillations can be exacerbated on the Ukrainian railways by the use of outdated rolling stock and rail irregularities caused by their wear and tear. All of this significantly limits the maximum permissible speeds on the tracks. To solve these problems, it is necessary to conduct research on rolling stock oscillations and their dependence on track irregularities. To this end, experts are constantly developing new mathematical and simulation models of rolling stock and upgrading existing ones, which saves time and resources on complex and sometimes dangerous real-world experiments.

II. Analysis of Recent Research and Publications

Modelling of oscillations in the vertical plane (bouncing and galloping) is usually performed by using a system of differential equations that describes these dynamic processes. The first main area of research on vertical oscillations is the study of their dependence on the stiffness and damping coefficients of the dampers of the first and second levels of car suspension or on the taper of the wheels [4−6]. The second direction is to study the dependence of oscillations on the condition of the railway track: ballast layer and rails [7−10]. Regardless of the ultimate goal of the research, in order to reproduce forced vertical oscillations, it is necessary to set a disturbance input in the form of a random irregularity of the rails [11].

Irregularities can be represented in several ways. Firstly, real data of irregularities existing on a particular section of track can be taken for modelling using track measuring wagons [11, 12]. This method most accurately reproduces the actual condition of the rails, but requires real-world experiments using specialised equipment and blocking the selected railway junctions, hence in many cases is not cost-effective. Given the lack of experimental data, scientists widely use an indirect method, which consists of simulating a random process that describes track irregularities by their power spectral density (PSD) [11, 13−16]. This method covers the entire frequency spectrum of the irregularities that are being analysed. An alternative option for irregularity simulation is to represent it as a signal consisting of the sum of only a few selected frequencies that are specific to a particular section of the track or that describe specific periodic types of irregularities, such as a joint irregularity [17].

In recent years, the use of neural networks in railway-related research has become increasingly popular. In addition to their classical use for storing information and problem-solving in the field of logistics and transportation management, they have also found their application in the analysis of data related to the calculation of passenger comfort [18], rolling stock oscillations and calculation of the forces of its interaction with the railway track [9, 10, 18].

The range of possibilities for using artificial neural networks has expanded significantly with the advent of so-called Deep Learning Neural Networks, which are

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

capable of modelling high-level abstractions using numerous nonlinear transformations. In recent years, recurrent neural networks have been actively used in the study of oscillations and forces arising during the train movement. In [10, 19], they are used to predict rolling stock oscillations. Convolutional neural networks are also used in [10, 20–22]. Their main application is to predict oscillations and forces in the wheel-rail contact.

Deep learning neural networks can also be used to generate stochastic processes by finding dependencies in the distribution of values that are invisible to the human eye [22, 23]. In [23], the authors developed a so-called Statistics-Informed Neural Network (SINN) framework based on a recurrent neural network, which is capable of learning the stochastic dynamics of a given signal and reproducing it by generating a free-length signal. Since railway track irregularities are stochastic in nature and can be reproduced based on their power spectral density and other statistical characteristics, SINN can be used to generate railway track irregularities caused by rail wear.

The goal of the paper is to perform modelling of random irregularities of a railway track section based on their power spectral density using a Statistics-Informed Neural Network. The generated irregularities will be further used to model the vertical oscillations of rolling stock, which are used to calculate the control laws in on-board decision support systems for drivers on Ukrainian railways.

III. Random Irregularities of the Railway Track

The values of railway track irregularities obtained using the methods of the theory of random functions are widely used as external disturbances for modelling the forced oscillations of rolling stock [11, 13, 14]. One of the most used approaches uses an equivalent geometric irregularity η with specified spectral characteristics [13 – 15]. The data collected by researchers from different countries demonstrate that track irregularities can be represented as a stationary ergodic random process. The main measured statistical characteristics of track irregularities are power spectral density and autocorrelation function (ACF).

The PSD is calculated as a function of frequencies $\omega = 2\pi/L_d$, where L_d is the wavelength of the irregularity [14]. For our model, we select the formula for calculating the PSD for German high-speed railways [14].

$$S_v(\omega) = \frac{A_v \omega_c^2}{(\omega^2 + \omega_r^2)(\omega^2 + \omega_s^2)}$$

where $S_v(\omega)$ is the PSD, m^2/rad/m; A_v is the vertical irregularity parameter, m rad; ω_c, ω_r, ω_s are frequency parameters, rad/m.

The numerical modelling of a random process of track irregularities with a given power spectral density using the trigonometric series method is conducted. Let the sample of irregularities be $\eta = \eta(x)$, where $\eta(x)$ is the track irregularity of coordinate x and is represented by a random function, the mean of $\eta(x)$ equals zero. The discrete function $\eta(x)$ can be approximated by the following trigonometric series:

$$\eta(x) = \sum_{k=1}^{N}(a_k \cos \omega_k x + b_k \sin \omega_k x) \quad (2)$$

where a_k, b_k are independent Gaussian random variables with mean 0 and standard deviation σ_k, and their values are independent of each other for $k = 1,2,...,N$.

$$\sigma_k^2 = 2S_v(\omega_k)\Delta\omega \quad (3)$$

$$\omega_k = \omega_{\min} + (k - \frac{1}{2})\Delta\omega \quad (4)$$

$$\Delta\omega = (\omega_{\max} - \omega_{\min})/N \quad (5)$$

The frequencies from the frequency spectrum ω_k are calculated using formula (4) for $k = 1, 2,...N$, where N is the total number of frequency increments in the $[\omega_{\min}, \omega_{\max}]$. The frequencies $\omega_{\min} = 2\pi/L_{d\,\max}$ and $\omega_{\max} = 2\pi/L_{d\,\min}$ are the minimum and maximum frequencies of the given frequency spectrum, respectively. $L_{d\,\min}$ and $L_{d\,\max}$ are the minimum and maximum wavelengths. $\Delta\omega$, used in equation (5), is the frequency increment over the interval $[\omega_{\min}, \omega_{\max}]$.

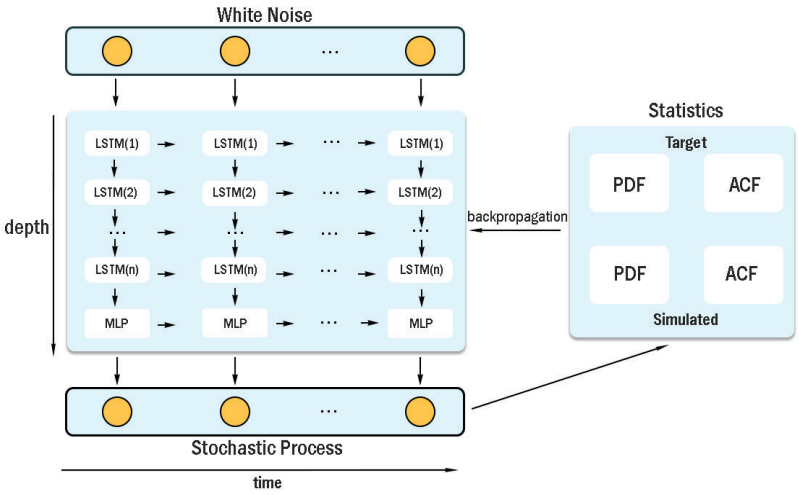

Fig. 1 SINN architecture

IV. Statistics-informed neural network

A. Neural network architecture

The structure of a statistics-informed neural network is shown in Fig. 1. It is based on several layers of a Long Short-Term Memory (LSTM) neural network. The output gate of the last LSTM layer is connected to a fully connected linear layer for data conversion.

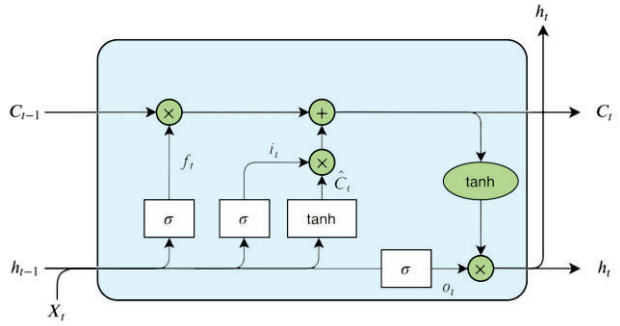

Fig 2. LSTM-cell structure

The input of the model is data with high entropy, i.e. white noise. It enters the first of a series of LSTM cells, each of which has the structure shown in Fig. 2. An LSTM cell has an input vector x_t; a hidden state vector h_t, which represents the network's "memory" and is initialised with zeros; a cell state c_t, which is responsible for storing long-term information; and three types of gates to control the flow of information in the network.

The first gate is the Forget gate. It accepts the past hidden state h_{t-1} and the current input x_t and outputs a vector of values scaled from 0 to 1, which indicate how much of the cell's previous state should be "forgotten". This gate allows the network to selectively delete and remember information from the previous step. The second gate is the Input gate, which takes the past hidden state h_{t-1} and the current input x_t and outputs a vector of values scaled from 0 to 1, which indicate which part of the input vector should be added to the cell state. This allows to choose whether to add or discard new information. The third gate is the Output gate. It takes the previous hidden state h_{t-1}, the input vector x_t, the current state of the cell c_t, as it's input and outputs a vector of values, and shows which part of the current state of the cell should be displayed as the current hidden state h_t. This allows to ignore parts of the cell state when calculating the output. At the output of each cell, an output vector y_t is generated, which in turn is fed to the input of the next LSTM cell.

The equation for the first LSTM cell in the SINN:

$$f_t^{(1)} = \sigma_g\left(W_f\xi_t + U_f h_{t-1}^{(1)} + b_f\right)$$

$$i_t^{(1)} = \sigma_g\left(W_i\xi_t + U_i h_{t-1}^{(1)} + b_i\right)$$

$$o_t^{(1)} = \sigma_g\left(W_o\xi_t + U_o h_{t-1}^{(1)} + b_o\right)$$

$$\hat{c}_t^{(1)} = \sigma_c\left(W_c\xi_t + U_c h_{t-1}^{(1)} + b_c\right)$$

$$c_t^{(1)} = f_t^{(1)} \circ c_{t-1}^{(1)} + i_t^{(1)} \circ \hat{c}_t^{(1)}$$

$$h_t^{(1)} = o_t^{(1)} \circ \sigma_h\left(c_t^{(1)}\right)$$

where ξ_t is the cell input vector represented as white noise; $c_t^{(1)}$ is the state of the first LSTM cell; $\hat{c}_t^{(1)}$ is the activation of the cell input; $f_t^{(1)}$, $i_t^{(1)}$, $o_t^{(1)}$ are the forget, input and output gates, respectively. W_f, U_f, W_i, U_i, W_o, U_o, W_c, U_c are the weight matrices of the forget, input, output gates and activation of the cell, b_f, b_i, b_o, b_c are the biases for the gates and activation; σ_g is a sigmoidal activation function; σ_c is a hyperbolic tangent.

The input of the next layer, instead of ξ_t, is the output of the previous layer $h_t^{(i-1)}$. The final output of the SINN is calculated as $X_t = W_m h_t^{(n)}$, where $h_t^{(n)}$ is the output of the n-th LSTM cell, W_m is the weighting matrix.

B. Loss Functions

To obtain the desired result in SINN, the statistics of the output signal must match the statistics of the target sample. These statistical characteristics include the autocorrelation function and the probability density function (PDF).

The autocorrelation function for a sequence X is a deterministic function of the delay τ, and is defined as:

$$ACF_X(\tau) = \frac{E[X_t X_{t+\tau}]}{E[X_t^2]}, \quad (6)$$

where the process X has zero mean.

There are two main methods for calculating the ACF. According to the first, the ACF for each τ is calculated using the formula (6). The second method is to use the Fast Fourier Transform (FFT) to calculate the ACF.

$$ACF_X = FFT^{-1}(FFT(X)FFT(X)^*),$$

where * is a complex conjugate.

The second approach, although faster, can be significantly inferior to the first in accuracy, especially for large values of τ. Both methods allow to propagate the ACF-based losses to the neural network model. The loss function for the autocorrelation function is calculated using formula (7). Here, $ACF_O(\tau)$ is the ACF of the original SINN signal at time τ, $ACF_T(\tau)$ is the ACF of the target stochastic process.

We calculate the probability density function for the original and desired signals using the kernel density estimation:

$$\hat{f}_h(x) = \frac{1}{|X|}\sum_i^{|X|} K_h(x - X_i)$$

where K is a non-negative kernel, h is a smoothing parameter. $K_h(d) \doteq \frac{1}{h}K\left(\frac{d}{h}\right)$ is the scaled kernel.

The loss function for the PDF is calculated by formula (8), where $\hat{f}_h^O(x)$ and $\hat{f}_h^T(x)$ are the PDF of the source sequence and the target stochastic process.

$$Loss_{acf} = \frac{1}{n}\sum_{\tau\in T}|ACF_O(\tau) - ACF_T(\tau)| + \frac{1}{n}\sum_{\tau\in T}[ACF_O(\tau) - ACF_T(\tau)]^2 \quad (7)$$

$$Loss_{pdf} = \frac{1}{n}\sum_{i=1}^{n}\left|\hat{f}_h^O(x_i) - \hat{f}_h^T(x_i)\right| + \frac{1}{n}\sum_{i=1}^{n}\left[\hat{f}_h^O(x_i) - \hat{f}_h^T(x_i)\right]^2 \quad (8)$$

V. Preparation for the Simulation

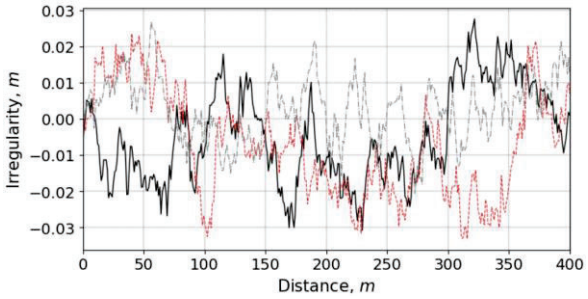

Fig. 3. Simulated track profile samples

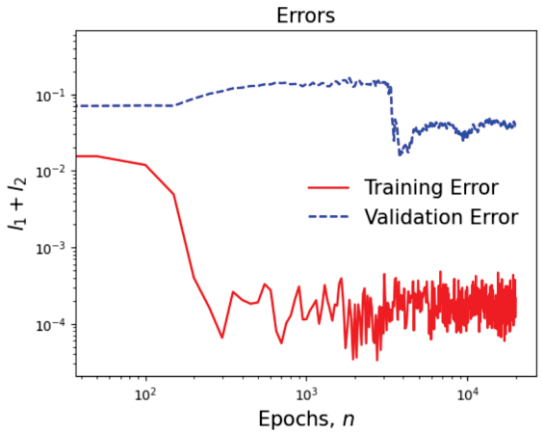
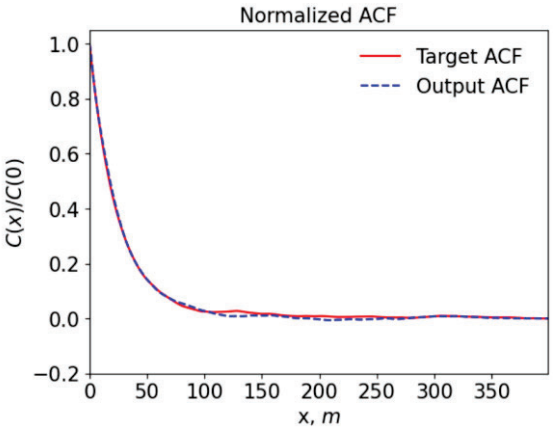
To collect the data for the training, a MATLAB program was created that calculates the trajectories of railway track irregularities using the trigonometric series method according to power spectral density calculated using formulas (1) and (2). The minimum and maximum wavelengths of the irregularities used in the calculations are $L_{d\,\min}$ = 0.5 m and $L_{d\,\max}$ = 50 m. The equation parameters were selected according to the recommendations for calculating irregularities of high interference level for high-speed railway transport of Germany: A_v = 10.80 10^{-7} m rad, ω_c = 0.8246 rad/m, ω_r = 0.0206 rad/m, ω_s = 0.4380 rad/m [14]. The number of frequency increments is N = 2000. The program generates trajectories for the target and validation samples. Three different realisations of the railway track trajectories with irregularities obtained using the developed programme are shown in Fig. 3.



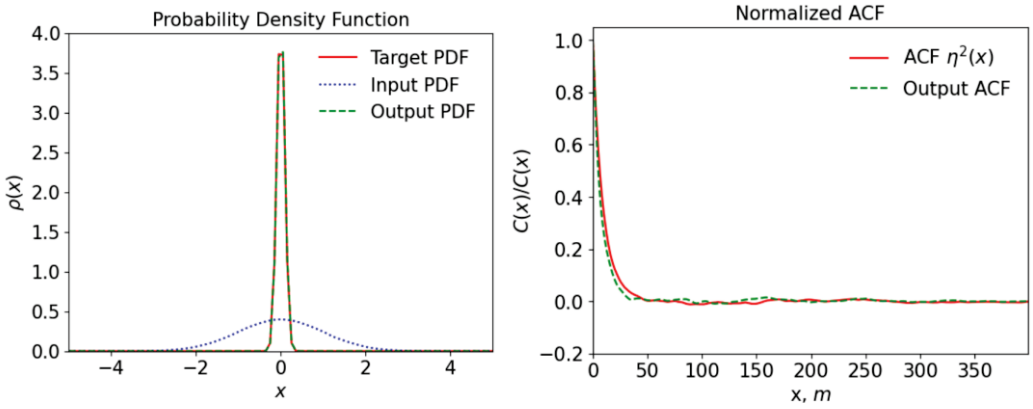
The SINN neural network was implemented in the Python programming language using the PyTorch machine-learning framework. The neural network is trained using stochastic gradient descent method with the Adam optimizer. The learning rate is set to 10^{-3}, with parameters β_1 = 0.9 and β_2 = 0.999. The values of the training and validation loss functions are calculated every 50 iterations during the training process.

The input data are trajectories consisting of Gaussian white noise and generated randomly for each new training of the network. The training, target, and validation samples each contain 400 separate process realisations, each consisting of 400 points. The validation sample was created to prevent overtraining of the neural network.



From the entire range of lags 1...t_{max}, a set T of lag values τ_1,..., τ_m is randomly selected at each step of the gradient descent, where $m << t_{max}$.

VI. Results of Neural Network Training



During the training, the network structure was chosen, namely four layers: an input layer, two hidden LSTM layers, and an output layer. The input and output layers have one neuron each, the first hidden layer contains 25 neurons, and the second hidden layer contains 5 neurons. Training was performed for 20 000 epochs. Fig. 4*a* shows the graphs of training and validation errors. Figs. 4*b* − 4*d* show the graphs of statistical characteristics of the target and the obtained processes. The graphs show that the autocorrelation functions of the target and the output samples have a high degree of convergence. The probability density function of the resulting sample fully reproduces the probability density function of the target process. Thus, the irregularity trajectories obtained by the SINN neural network have the desired statistical characteristics.

c) *d*)

Fig. 4. Results of neural network training. a) Training and validation errors; b) Normalized ACFs; c) Probability density function; d) Normalized ACF for η^2

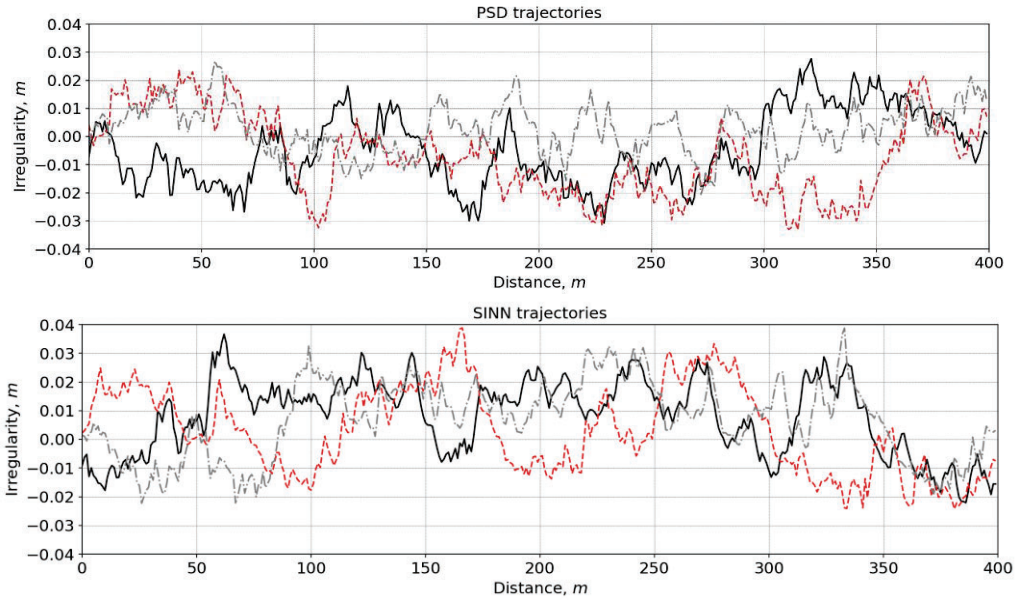

Fig. 5. Simulated irregularities of railway track

The samples obtained with PSD and those obtained with SINN are shown in Fig. 5.

The irregularity trajectories on a 400-meter long section obtained using the neural network have the same statistical characteristics as the target trajectories, the same amplitude ranges, and are generally similar to the implementations reported in the literature [13, 14].

The trained neural network is also capable of generating trajectories that are longer than those of the target sample. The implementation of such a long-term trajectory for a 1200-meter long path section is shown in Fig. 6. Such trajectories can be used as a disturbance input to calculate the vertical oscillations of the rolling stock on a track section of arbitrary length.

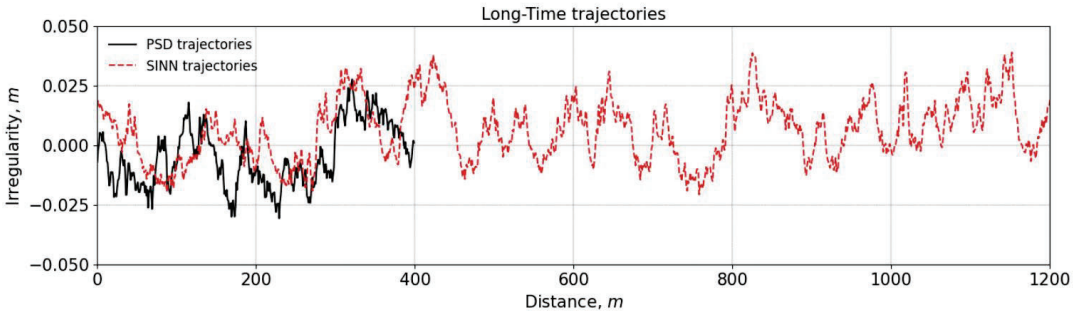

Fig. 6. Long-time track profile trajectories

VII. Conclusions

In this paper, analysis of the main causes of vertical oscillations of a train is carried out. It is proposed to analyse the dependence of oscillations on track irregularities. For this purpose, a review of methods for modelling the track profile and the use of neural networks for generating stochastic processes was performed. It was decided to use a statistics-informed neural network to generate irregularity trajectories.

To collect samples for training the neural network, a program was developed that calculates the power spectral density of the desired signal and generates short-term samples of path irregularities based on the trigonometric series method. In the course of the experiments, the structure and parameters of the statistics-informed neural network are chosen. The statistical characteristics of the desired stochastic process for training the neural network are obtained from previously generated training sample. The trained neural network generates samples of railway track irregularities that are close to real ones. The neural network is able to generate irregularity trajectories that are longer than the training samples, while maintaining the characteristics of the desired stochastic process, and therefore can be used to model irregularity on sections of arbitrary lengths.

The resulting neural network can be used to model irregularity on long sections of railway track and further applied in a complex model of vertical oscillations of rolling stock for on-board decision support systems that calculate optimal control actions of a train on a given section of track.

Abstract*—The article analyzes the causes of emergency conditions in shipboard alternating current (AC) electric power systems. It focuses on how external failures, such as phase disconnection or voltage drops, can lead to internal malfunctions and a cascading chain of damage. The author explains specific failure mechanisms. For example, exceeding current limits in rectifiers can cause internal short circuits due to thermal breakdown, while inverter backfeeding leads to increased power switch-off times. The article emphasizes that the thermal regime of components, which depends on geometric dimensions and current pulse frequency, is a critical factor. To study the dynamics of defect propagation, the article proposes developing a model that can evaluate the sequence and speed of damage spread. This model would use simplifying assumptions like network symmetry and linear resistance. The author also suggests using time-domain diagrams of voltages and currents to demonstrate different fault types. The text lists common failures, including short circuits of semiconductor modules, inverter and control module failures, and interphase short circuits. It concludes by discussing diagnostic methods, proposing that voltages and currents across power valves be used as primary diagnostic parameters because their variations indirectly reflect the thermal conditions of components. The loss of control in one valve is highlighted as a factor that increases the load on others, promoting overheat.

I. Introduction

Modern shipboard power systems are increasingly utilizing frequency converters (FCs) to enable efficient and flexible control of electric drives, automation systems, and other onboard equipment. The reliability and uninterrupted operation of FCs are critically important for the safety of the vessel and its ability to perform designated functions. Therefore, the issue of timely and accurate diagnostics of their condition has become particularly relevant. This literature review covers current trends and methods employed for diagnosing shipboard frequency converters.

One of the key trends in the diagnostics of frequency converters is the shift from traditional methods based on periodic inspections and measurements to more proactive and intelligent approaches. This includes the implementation of continuous monitoring systems that track key FC performance parameters in real time, such as current, voltage, temperature, frequency, and vibration.

The diagnostic methods currently under active research and application can be classified as follows:

Electrical signal analysis: This approach is among the most widely used and involves analyzing current and voltage at the input and output of the FC. Spectral analysis techniques, such as Fast Fourier Transform (FFT), allow for the detection of characteristic harmonics that indicate specific faults, such as short circuits, open circuits in power semiconductors, or failures of DC-link capacitors [1].

Thermal monitoring: An increase in temperature is one of the primary indicators of faults in FCs. The use of thermal imaging cameras and temperature sensors enables the detection of overheating in specific components, which may indicate performance degradation or impending failure [2].

Vibration analysis: Mechanical damage to cooling fan bearings or uneven loading of power modules can lead to elevated vibration levels. Vibration spectrum analysis enables early identification of such issues [3].

Model-based diagnostics: This approach involves developing mathematical models of the FC, which are used for comparison with actual measurements. Deviations between the model and real data can point to the presence of faults. The development of machine learning techniques has enabled the creation of more accurate and adaptive models for diagnostics [4].

Artificial intelligence (AI) and machine learning (ML)-based diagnostics: AI and ML algorithms, such as artificial neural networks, decision trees, and support vector machines, are increasingly being used to analyze large volumes of data obtained from monitoring systems. These methods make it possible to detect complex patterns and accurately predict future failures [5].

Modern shipboard power systems increasingly rely on frequency converters to provide efficient and flexible control of a wide range of onboard equipment. The safe operation of the vessel, the functionality of critical systems, and the overall operational efficiency are directly dependent on the reliable performance of these converters. Despite significant advancements in the development and implementation of diagnostic methods for FCs, there remains an urgent need for further research to address existing challenges and to expand the capabilities of monitoring and fault prediction systems.

Modern diagnostic methods include electrical signal analysis, thermal and vibration monitoring, model-based diagnostics, and approaches based on artificial intelligence

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

and machine learning. However, the integration of these heterogeneous methods into a single, comprehensive diagnostic system remains a complex challenge [6]. Data obtained from various sensors and monitoring systems are often unstructured and require sophisticated processing and correlation algorithms to produce a coherent picture of the FC's condition.

Moreover, the specific operational conditions of shipboard FCs—such as exposure to aggressive marine environments (humidity, salt mist, vibration from main engines and wave impacts)—impose additional demands on the reliability and robustness of diagnostic systems [7]. Sensors and monitoring equipment must be protected against corrosion, vibration, and electromagnetic interference, which may limit the choice of available technologies and increase the cost of implementation.

Another critical aspect is the need to develop more accurate and predictive fault models. Most existing methods focus on detecting already existing defects, whereas the ability to predict future failures at an early stage would enable timely preventive maintenance, minimize vessel downtime, and prevent emergency situations [8, 9]. Achieving this goal requires deeper research into the mechanisms of fault occurrence and development in shipboard FCs, considering their specific operating conditions.

The advancement of AI and ML technologies opens new prospects for improving FC diagnostic systems. However, the effective application of these methods requires large volumes of high-quality data on FC operation under various modes and fault conditions. The collection and sharing of such data among different vessels and operators may be hindered by confidentiality concerns and the lack of standardized protocols [10, 11]. Therefore, further research should focus on developing efficient methods for collecting, processing, and exchanging diagnostic data, as well as on creating adaptive AI algorithms capable of learning from limited datasets while considering the specific characteristics of particular FC types and their operational environments.

Additionally, there is a need to design simpler and more cost-effective diagnostic systems that are accessible to a broader range of vessels, including smaller ships. Many of the current advanced methods are complex and expensive to implement, limiting their applicability on low-tonnage vessels.

II. Enhancing the Efficiency and Reliability of Operation of the Shipboard Unified Alternating Current Power System

The causes of external faults are located beyond the boundaries of the control system of the ship's power system and the power circuits of the valve complexes of this system. Given this, if external defects (emergency processes) are not immediately eliminated, this usually leads to the further development of internal critical conditions within the shipboard unified AC power system.

If the overload current values exceed the permissible operating currents of an individual ship rectifier, this creates conditions for internal short circuits. This becomes possible due to thermal breakdown caused by a significant temperature rise in the structure of the rectifier's valve. Such a situation can lead to a hard short circuit at the rectifier's output terminals.

The backfeeding of the ship inverter causes current oversaturation of the inverter, which leads to an increase in the switch-off time of the power keys beyond their nominal values. For such a failure to occur, one of the phases must be disconnected or the voltage in the ship's AC network must drop below the nominal level.

The load-carrying capacity of the valves is determined by their thermal operating mode, which depends on their geometric dimensions, duration of exposure, and the frequency range of anode current pulses. Analysis of modes caused by emergency situations in these conditions requires calculating the overload currents and understanding the potential thermal operating regimes of the power valves under these load conditions.

To clearly study the development of defects during the operation of the unified shipboard AC power system, it is necessary to develop a model of emergency mode propagation. This model will allow us to illustrate the dynamics of damage propagation and make it possible to evaluate the sequence and speed of the spread of emergency processes.

To identify specific types of failures that occur in the ship's AC power system, we will consider the following rectifier operating modes:

– short circuit of the semiconductor module;
– open circuit of the semiconductor module;
– inverter failure due to excessive current loads or malfunctions in the control system;
– interphase short circuit in the winding;
– malfunction or complete failure of the control module;
– break in the phase winding;
– failure of the power element of a switch.

To construct the model, we establish the following assumptions:

– the three-phase network is symmetrical;
– the active and inductive resistances in the circuits are linear;
– the electromotive force is sinusoidal and has a constant amplitude.

The models are represented as time diagrams of voltages and currents, which clearly illustrate the failure types listed above.

Let us consider, based on a standalone inverter, a model of a valve pair (Fig. 1) [12, 13].

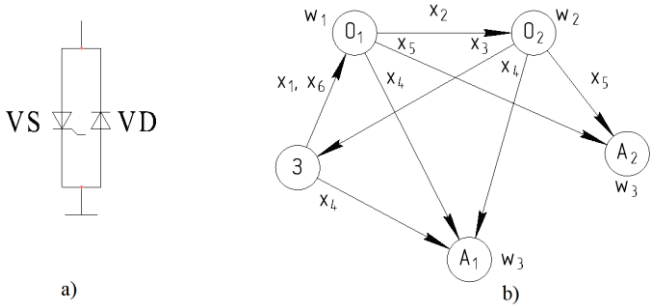

Fig. 1. The model of a a valve pair

a) valve pair;

b) types of transitions

The valve pair is considered as a Moore finite state machine.

The input and output signals are given in Tables 1 and 2.

TABLE I. INPUT SIGNALS

Code Value	*Description*
$x_1(i_y \neq 0)$	control signal present
$x_2(i_y \prec 0)$	thyristor off and diode on
$x_3(i_y \succ 0)$	full switch off
$x_4(i_y = 0)$	valve failure
$x_5(i_y \neq i_{кз})$	alve breakdown (short circuit)
$x_6(u_i \succ 0)$	positive voltage present at the valve

TABLE II. OUTPUT SIGNALS

Code Value	*Description*
w_1	$i_T(t);\ u_T(t)$
w_2	$i_D(t);\ u_D(t)$
w_3	alarm signal $i_{short\ circuit}$

Table 3 lists the possible states of the valve pair.

TABLE III. VALVE PAIR STATES

Encoded Value	*Description*
3	closed state
O1	thyristor conduction state
O2	diode conduction state
A1	fault (due to open circuit, one of the valves failed)
A2	fault (due to breakdown, one of the valves failed)

It is possible to divide the emergency transient process in the ship rectifier into intervals depending on the number of phases participating in current conduction. For any interval, the equivalent circuit changes at its boundaries but remains constant within the interval.

Initial conditions for the currents at each moment are set based on the final conditions from the previous interval. The "short circuit" mode arises in the ship's converter circuit during the breakdown of a power switch. Let us assume that Power Valve 1 has failed (shorted), and the emergency process begins only when Power Valve 3 opens—an internal short-circuited loop is formed in the circuit. The current, under the influence of line EMF e_{2ab}, flows through thyristors V1 and V3. A two-phase short circuit loop forms between phases e_{2a} and e_{2b} (Power Valves 1 and 3)—see Fig. 2a.

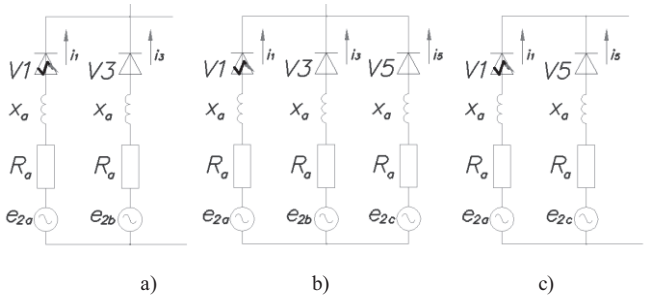

Fig. 2. Short circuit occurrence between phases

At the moment a valve from the group of damaged power switches opens (in this case, Power Valve 5), a three-phase short circuit occurs—not between two, but all three phases (e_{2a}, e_{2b}, and e_{2c}) – see Fig. 2b.

The three-phase short circuit mode continues until the current in Power Valve 3 drops to zero. Once the current in Valve 3 reaches zero, the three-phase short circuit transitions into a two-phase short circuit between phases e_{2a} and e_{2c} (Power Valves 1 and 5) – see Fig. 2c.

In the circuits where the short circuit occurred, the current values are limited only by the active resistance of the ship's power transmission line Ra. During the creation of an internal short circuit, overcurrents of emergency overload appear starting from the first period of the supply network voltage waveform.

In a bridge inverter circuit that uses counter-parallel diodes, similar processes occur when semiconductor modules are shorted. The equivalent circuit of the inverter in this mode is shown in Fig. 3, where Z_n – the load resistance, L_k and C_k – inductance and capacitance of the inverter oscillatory circuit and C_p – the capacitance of the capacitor connected in parallel to the transformer winding.

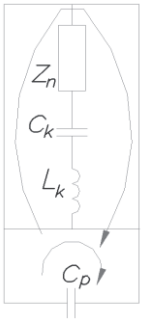

Fig. 3. Equivalent circuit of the shipboard converter during a short circuit of the semiconductor module

The formation of short-circuited loops causes a redistribution of energy reserves. Very high current values arise, resulting in significant overloads on reactive components.

These emergency conditions develop in an avalanche-like manner, with extremely high rates of current and voltage rise in the circuit elements. They are accompanied by significant overvoltages and excessively high currents in the inductive components. These currents pose a serious

threat to the valves and wires of the ship's electrical system, especially in powerful installations with thin wire terminations.

The duration of emergency processes typically lasts one control period. Protection from the development of these negative conditions is only possible through the use of modern protection systems. Such systems in real converters include protection channels. Protection devices that can disconnect circuits with fault currents help to shorten the duration and magnitude of overcurrents, thus reducing the severity of the emergency condition.

Table 4 presents the results of emergency mode analysis in the form of cause-and-effect relationships. It compares diagnostic signs with the causes that triggered their appearance.

Table 4 shows that it is impossible to link each specific type of failure to external defects in the power circuits. This is explained by the fact that electrical circuits are continuous networks, and any failure in one part of the circuit leads to a new redistribution of current values in all branches, affecting the operation of all components and worsening their performance.

Diagnosing shipboard power systems is most appropriate in the signal space. In this case, diagnostic indicators include currents, voltages, and their derivatives measured at several control points in the ship's electrical network. When diagnosing complex ship subsystems, each of them may use its own variant of indicator evaluation (e.g., full state information, evaluation of only input and output signals, partial evaluation, or evaluation based solely on output signals).

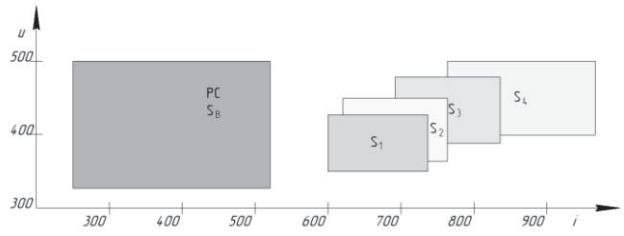

Fig. 4. Relationship of External Indicators and States for Power Inverter Valves

The consideration of interrelations between the states of the inverter power circuit (see Fig. 4) and external signs (such as voltage and current values on the power valves of the inverter) does not imply a one-to-one correspondence between them.

The subsystems of shipboard power systems consist of a large number of components. The condition of each component is determined by its own diagnostic parameters. Semiconductor elements are monitored through parameters such as the rate of current and voltage rise on the valves, recovery time of control properties, and temperature. Capacitors, inductors, and resistors can be monitored by tracking values such as capacitance loss, inductance loss, and resistance loss respectively. However, because the weakest elements in power circuits are the semiconductor valve elements, we will use the parameters listed in Table 5 as diagnostic parameters for assessing the health of these circuits.

TABLE IV. RELATIONSHIP BETWEEN CAUSE AND EXTERNAL INDICATORS FOR POWER INVERTER VALVES

Cause	External Indicator										
	No power	*Current decrease*	*No current*	*Voltage decrease*	*No voltage*	*Temporary loss of output voltage*	*Appearance of pulsations*	*Increase in the rate of rise of du/dt*	*Increase in the steepness of the rise of di/dt*	*Generation of short-circuit currents on the valves*	*Uneven current loading of the valves*

Open circuit in power valve S2							+				
Open circuit in power valve B						+	+				
Open circuit in supply circuit			+		+						
Open circuit in phase winding B	+	+		+							

For the cooling unit, it is sufficient to measure only the output quantity (pressure or flow rate of the cooling fluid). For the control system, it is necessary to detect the presence or absence of control pulses and their parameters, which makes it convenient to assess functionality based on the parameters of the components comprising the system. To

predict the system's condition and detect gradual failures, it is advisable to use diagnostics based on parameters.

TABLE V. PARAMETERS CHARACTERIZING THE CONDITION OF SHIPBOARD POWER SYSTEMS

Subsystem	Diagnostic Parameters of Elements						
	$\frac{du}{dt}$	$\frac{di}{dt}$	$t_в$	*Temperature*	*Resistance*	*Pressure*	*the feedback signal*
Power circuits	+	+	+	+	+	–	–
Cooling subsystem	–	–	–	–	–	+	–
Control, protection devices	–	–	–	–	–	–	+

Malfunctions in the power circuit of a ship converter occur due to the formation of short-circuited loops, which cause redistribution of currents and loads among individual components and branches of the circuit. The loss of control in one of the parallel valves increases the current stress on the remaining ones. Higher current through the semiconductor elements leads to overheating, gradually degrading the valve structure. Overheating may result in insulation failure, which means that temperature conditions can be indirectly monitored by observing the current. If one of the series-connected valves fails, the voltage across the remaining ones rises, further reducing their reliability, which confirms the research assumptions [14-16]. Therefore, since it is difficult to directly measure parameters such as temperature or bulk resistance of semiconductor structures, the most informative diagnostic indicators of ship power systems are the currents and voltages across the power valves , which confirms the research assumptions [17-19] and which confirms the findings of the research [20, 21].

VI. CONCLUSIONS

Failures in the power circuit of the ship converter are associated with the emergence of short-circuited loops, which lead to the redistribution of currents and loads across individual components and circuit branches. Loss of control in one of the parallel valves increases the current load on the remaining ones. An increase in currents flowing through the semiconductor elements of the circuit causes excessive heating of components included in the circuit, which, in turn, leads to gradual degradation of the valve structure. As a result of overheating, insulation breakdown may occur, meaning that temperature conditions can be indirectly tracked by monitoring current. If one of the series-connected valves fails (breaks down), the voltage across the remaining ones increases, which also reduces the reliability of the elements.

Therefore, given the difficulties in directly measuring parameters such as temperature and bulk resistance of semiconductor structures, currents and voltages on the power valves are chosen as the diagnostic parameters that best characterize the state of shipboard power systems.

***Abstract* — For a frequency-regulated surface permanent magnet synchronous motor a refined calculation of the main electromagnetic power losses is proposed, which simultaneously takes into account all types of main power losses present in this motor, as well as the components of electrical losses caused by the transportation of magnetic power losses to the magnetization circuit and additional power losses through the air gap of this motor, respectively. Based on the obtained refined calculation dependencies for this motor its electromagnetic processes and energy characteristics (main electromagnetic power losses, main consumed active power, efficiency and power factor) are quantitatively estimated in steady operating modes of the mentioned motor at the different values of the speed and useful torque on the motor shaft.**

Keywords — surface permanent magnet synchronous motor, main electromagnetic power losses, frequency regulation.

I. INTRODUCTION

Due to the development of industrial production and wide implementation in various branches of the economy of frequency-regulated (f-r) synchronous motors with permanent magnets installed inside (IPMSM – Interior Permanent Magnet Synchronous Machine) or on the surface (SPMSM – Surface Permanent Magnet Synchronous Machine) of the rotor of these motors, now in practice there is an actual called for a refined calculation of the energy characteristics of these motors with frequency regulation in a wide range of speed and load changes. Based on the now observed rise in the cost of electricity in the world and Ukraine, a refined definition of the energy characteristics of these motors will allow subsequently to optimize (minimize) their operating modes in exploitation, thereby reducing power losses in them and their overall electricity consumption.

Despite of the existence of known publications devoted to the calculation and research of energy modes of IPMSM and SPMSM, all of them have a number of shortcomings that reduce the precision of calculating their electromagnetic and energy processes. In particular, in monographs [1, 2] and article [3], additional power losses always are not taken into account when calculation of power losses are realized in these motors. In contrast to these publications, in monograph [4] and articles [5–8] in the calculation: power losses of the mentioned motors, all types of main power losses present in them (including additional power losses) are taken into by the transportation of magnetic power losses to the magnetization circuit of the motors; however, the component of electrical losses caused by the transportation of additional power losses through the air gap of the motors, is not taken into account in the calculations.

The purpose of the article is to obtain analytical dependencies for a more precise calculation of the stator current and the main electromagnetic power losses of a three-phase SPMSM and to research, using the obtained more precise dependencies, the steady main electromagnetic and energy processes of this motor in the operating ranges of its speed and load changes.

II. INITIAL ASSUMPTIONS

a) three-phase stator and rotor windings for different phases of the motor are made mutually symmetrical and constructional identical;

b) the motor air gap is the same along the entire inner circumference of the stator;

c) there is no zero sequence in the three-phase system of stator supply voltages (currents) of the motor;

d) internal parameters of the motor circuit: the active resistance R_s of the stator winding (which corresponds to the motor operating temperature) and for SPMSM equal to each other dissipation inductances: $L_{\sigma s.d} = L_{\sigma s.q} = L_{\sigma s}$ and magnetizing inductances: $L_{md} = L_{mq} = L_m$ along the longitudinal «d» and transverse «q» axes of this motor – were assumed to be unchanged;

e) only the main (caused by the first harmonic components of the phase stator voltages and currents) total power losses ΔP_m SPMSM were taken into account, which contain the following instantaneous losses components [4 – 8]:

- electrical ΔP^*_e (in the three-phase stator winding);
- magnetic ΔP_{ir} (in steel of the stator core);
- mechanical ΔP_{mech} (caused by friction in the motor shaft bearings and to self-ventilation);
- additional ΔP_{ad} (caused in the air gap of the motor by magnetic induction pulsations in the stator teeth).

For further simplification of analytical dependencies, describing electromechanical and energy parameters of the SPMSM mode, the method of generalized vectors [1, 2, 5] and the known relative system of units, accepted for

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

alternating current electric machines [5], were used. The researches were carried out by the method of computer simulation modelling.

The mentioned electrical ΔP^*_{e} (in stator winding), magnetic ΔP_{ir}, additional ΔP_{ad} and mechanical ΔP_{mech} types of main power losses, as well as main electromagnetic ΔP^*_{em} and total ΔP_m power losses, instantaneous η and nominal η_n values of motor efficiency, instantaneous values of electromagnetic power P_{em} and power factor $\cos(\varphi)$ SPMSM are determined from known analytical dependencies [5, 8 – 10]:

$$\left.\begin{aligned}
&\Delta P^*_{e}= R_s\cdot I_s^2,\ \ \Delta P_{e.n} = R_s\cdot I_{s.n}^{\ 2}, R_{ad} = \Delta P_{ad.n}/I_{sn}^2,\\
&P_{1.n} = \frac{P_{2.n}}{\eta_n},\ \Delta P_{i\,r} = \Delta P_{i\,r.n}\left(\frac{\Psi_m}{\Psi_{m.n}}\right)^2\left(\frac{\omega_1}{\omega_{1n}}\right)^{\lambda},\\
&\Delta P_{ad.n} = P_{1.n} - \Delta P_{e.n} - \Delta P_{i\,r.n} - \Delta P_{mech.n}, \omega_s = n/n_n,\\
&\Delta P_{ad} = R_{ad}\omega_s^2 I_s^2,\ \Delta P_{mech} = \Delta P_{mech.n}\cdot(\omega_s/\omega_{sn})^2,\\
&\Delta T_{mech} = \Delta T_{mech.n}\cdot\left(\frac{\omega}{\omega_n}\right),\ \Delta T_{mech.n} = \frac{\Delta P_{mech.n}}{\omega_n},\\
&\Delta P_{em}^{\ *} = \Delta P^*_{e} + \Delta P_{i\,r} + \Delta P_{ad},\ \cos\varphi = P_1/U_s I_s,\\
&\eta = \begin{cases} P_2/P_1 & \text{at } T \ge 0,\\ P_1/P_2 & \text{at } T < 0; \end{cases}\quad \eta_n = P_{2n}/P_{1n},\\
&P_2 = \omega T,\ \ P_1 = P_2 + \Delta P_m, \Delta P_m = \Delta P_{em} + \Delta P_{mech},\\
&P_{em} = P_1 - \Delta P^*_{e} - \Delta P_{i\,r} = \omega\cdot(T + \Delta T_{mech}) + \Delta P_{ad}.
\end{aligned}\right\} \quad (1)$$

In formula (1) the following notations are used: R_s – active resistance of the phase stator winding; I_s and I_{sn} – respectively instantaneous and nominal values of the module of the generalized vector stator current $\bar{I}_s$ of the motor (in the accepted relative system of units: I_{sn} = 1 r.u.); Ψ_m and Ψ_{mn} –respectively instantaneous and nominal values of the module of generalized vector $\overline{\Phi}_m$ of magnetic flux SPMSM; n and n_n – instantaneous and nominal values of speed [rpm] of the motor respectively; ω_s and ω_{sn} – respectively instantaneous and nominal values of the module of angular frequency of phase stator voltages and currents of the motor (which in steady modes in the accepted relative system of units are respectively equal to the instantaneous ω and nominal ω_h values of angular frequency of rotation of the rotor of the motor; the values of ω_{sn} and ω_h are equal to 1r.u.); λ –coefficient, which takes into account the change of magnetic power losses ΔP_{ir} SPMSM from the angular frequency ω_s of the stator magnetic field [5, 9] (for the researched motor in the article: λ = 1.55); $\Delta P_{e.n}$, $\Delta P_{ir.n}$ and $\Delta P_{mech.n}$ – nominal values (inherent in the nominal mode of SPMSM operation) of electric, magnetic and mechanical power losses of the motor, respectively; R_{ad} – equivalent active resistance to account the additional power losses ΔP_{ad} SPMSM; P_1 and P_{1n} – instantaneous and nominal values of consumed active power of the motor respectively; P_2 and P_{2n} – instantaneous and nominal values of useful power on the motor shaft; ΔT_{mech} and $\Delta T_{mech.n}$ – instantaneous and nominal values of mechanical losses of motor torque respectively; T and $(T+\Delta T_{mech.n})$ – instantaneous values of useful on the shaft and rotating torques of this motor respectively (positive values of torque T correspond to motor, and negative – to generator mode of SPMSM operation).

In steady modes of operation of the f-r SPMSM, the most convenient and sufficiently precise calculation of its electromagnetic processes is realized from the known analytical dependences [5]:

$$\left.\begin{aligned}
&U_{sd} = R_s I_{sd} + j\omega_s L_{\sigma s} I_{sd} + j\omega_s L_m I_{1d} - \omega_s L_m I_{1q},\\
&U_{sq} = R_s I_{sq} + j\omega_s L_{\sigma s} I_{sq} + j\omega_s L_m I_{1q} +\\
&+ \omega_s\left(L_m I_1 + \Psi_f\right),\ \Psi_{mn} = \sqrt{\Psi_f^2 + \left(L_m I_{1q.n}\right)^2},\\
&U_s = \sqrt{U_{sd}^2 + U_{sq}^2},\ I_{md} = I_f - I_{1d},\ \ I_{mq} = I_{1q},\\
&I_f = \Psi_f/L_m,\ \ U_f = \omega_s\cdot\Psi_f,\ \ I_s = \sqrt{I_{sd}^2 + I_{sq}^2},\\
&I_m = \sqrt{I_{md}^2 + I_{mq}^2},\ T + \Delta T_{mech} = \Phi_{md}\cdot I_{1q},\\
&\Phi_{mq} = L_m I_{1q}, \Phi_{md} = \Psi_f + L_m I_{1d}, \Phi_m = \sqrt{\Phi_{md}^2 + \Phi_{mq}^2}
\end{aligned}\right\}, (2)$$

in which generalized vectors (stator voltage $\overline{U}_s$ and current $\bar{I}_1$ or $\bar{I}_s$, magnetic flux $\overline{\Phi}_m$ and magnetizing current $\bar{I}_m$) were set through projections (respectively: U_{sd} and U_{sq}, I_{1d} and I_{1q} or I_{sd} and I_{sq}, Φ_{md} and Φ_{mq}, I_{md} and I_{mq}) on the axes of the rotating orthogonal coordinate system (OCS) «d-q», oriented by the real (longitudinal) axis «d» in the direction of the geometric axis of the magnetic field, created by permanent magnets installed on the motor rotor.

In publications [3, 7], due to the use of equivalent SPMSM substitution diagrams together with dependences (2) (containing additionally equivalent resistors, simulating the presence of magnetic power losses in the motor), the mentioned power losses are taken into account. At the same time, the instantaneous values of I_{sd} and I_{sq} projections of the generalized stator current vector are determined, in which the component of electric power losses of the motor, caused by the transportation of its magnetic power losses to the magnetizing circuit, is also taken into account. The deficiency of the calculations, proposed in these publications, is that they do not take into account the component of electric losses, caused by the transportation of the additional power losses through the SPMSM air gap.

In formula (2) the following notations are applied: Ψ_f and i_f – are the rotor magnetic flux and SPMSM excitation current, respectively, generated by permanent magnets; I_1, I_{1d} and I_{1q} – are the modulus, longitudinal and transverse projections of the generalized stator current vector $\bar{I}_1$, corresponding to the idealized SPMSM representation (when magnetic and addional power losses are not taken into account); Ψ_m and I_m – modules of the generalized vectors of magnetic flux $\overline{\Psi}_m$ and magnetizing current $\bar{I}_m$, respectively; j – imaginary unit (by means of which, when the vector diagram is graphically constructing, the sections of projections of vectors turn by 90 electrical degrees against the clockwise direction [5]). The vector diagram for SPMSM constructed from dependences (2) is presented in Fig. 1 for the second speed zone.

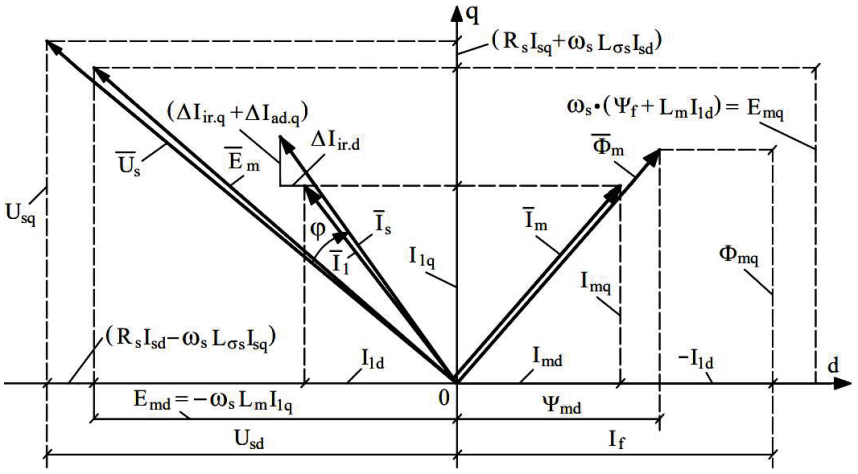

Fig. 1. Vector diagram for steady motor mode of operation (at $I_{1d} < 0$ and $\omega_s > \omega_{sn}$) of SPMSM

III. REFINED CALCULATED ANALYTICAL DEPENDENCIES

We selected known ones and obtained new refined analytical dependencies for calculation the instantaneous values of projections I_{sd} , I_{sq} and modulus I_s of the generalized stator current vector $\bar{I}_s$ SPMSM, which simultaneously take into account all the main power losses present in this motor, as well as the stator current increments, caused by transportation of magnetic power losses ΔP_{ir} to the magnetizing circuit and additional power losses ΔP_{ad} through the air gap of the motor.

Based on the dependence for the instantaneous magnetic power losses ΔP_{ir} in (1) and known relations [5, 8, 9]:

$$\left.\begin{aligned} &\Delta P_{ir} = \Delta P_{ir.n} \cdot \left(\Psi_m / \Psi_{mn}\right)^2 \cdot \left(\omega_s / \omega_{sn}\right)^{\lambda} = \\ &= \Delta P_{ir.n} \cdot \left(E_m / E_{mn}\right)^2 \cdot \left(\omega_s / \omega_{sn}\right)^{\lambda-2}, \\ &E_m = \omega_s \cdot \Psi_m, \quad E_{mn} = \omega_{sn} \cdot \Psi_{mn} \end{aligned}\right\} \qquad (3)$$

for the instantaneous E_m and nominal E_{mn} values of modulus of the SPMSM generalized electromotive magnetization force (EMF) vector $\bar{E}_m$, let us make an energy balance for the instantaneous magnetic power losses of this motor:

$$\left.\begin{aligned} &\Delta P_{ir} = \Delta P_{ir.d} + \Delta P_{ir.q}, \; E_m = \sqrt{E_{md}^2 + E_{mq}^2}, \\ &E_{md} = -\omega_s L_m I_{1q}, E_{mq} = \omega_s \cdot \left(\Psi_f + L_m I_{1d}\right), \\ &\Delta P_{ir.d} = \Delta P_{ir.n} \cdot \left(E_{md} / E_{mn}\right)^2 \cdot \left(\omega_s / \omega_{sn}\right)^{\lambda-2}, \\ &\Delta P_{ir.q} = \Delta P_{ir.n} \cdot \left(E_{mq} / E_{mn}\right)^2 \cdot \left(\omega_s / \omega_{sn}\right)^{\lambda-2} \end{aligned}\right\}, \qquad (4)$$

where $\Delta P_{ir.d}$ and $\Delta P_{ir.q}$ – are the components of the instantaneous magnetic power losses of the SPMSM along the longitudinal and transverse axes, respectively; E_{md} and E_{mq} – are the projections of the instantaneous generalized vector of the EMF $\bar{E}_m$ on the longitudinal and transverse axes of the rotating OCS «d – q», respectively.

Let us determine, based on (3), for SPMSM from the expression:

$$R_{ir} = \frac{E_m^2}{\Delta P_{ir}} = \frac{E_{mn}^2}{\Delta P_{ir.n}} \cdot \left(\frac{\omega_{sn}}{\omega_s}\right)^{\lambda-2} \qquad (5)$$

equivalent active resistance R_{ir}, which in the substitution diagrams of this motor [3, 7 – 9] simulates the instantaneous value ΔP_{ir} of its magnetic power losses.

Taking into account (4) and (5), we obtain analytical dependencies:

$$\left.\begin{aligned} \Delta I_{ir.d} &= \frac{E_{md}}{R_{ir}} = \frac{E_{md} \cdot \Delta P_{ir.n}}{E_{mn}^2} \cdot \left(\frac{\omega_s}{\omega_{sn}}\right)^{\lambda-2}, \\ \Delta I_{ir.q} &= \frac{E_{mq}}{R_{ir}} = \frac{E_{mq} \cdot \Delta P_{ir.n}}{E_{mn}^2} \cdot \left(\frac{\omega_s}{\omega_{sn}}\right)^{\lambda-2} \end{aligned}\right\} \qquad (6)$$

to determine the increments $\Delta I_{ir.d}$ and $\Delta I_{ir.q}$, respectively, for the longitudinal and transverse projections of the generalized $\bar{I}_s$ SPMSM stator current vector, caused by transporting its magnetic power losses to the motor magnetizing circuit.

After subtraction the above mentioned increments $\Delta I_{ir.d}$ and $\Delta I_{ir.q}$ from the generalized stator current vector $\bar{I}_s$, we obtain the following generalized vector $\bar{I}_{1\Sigma}$, which calculated from the relations:

$$\left.\begin{aligned} &\bar{I}_{1\Sigma} = I_{1\Sigma d} + jI_{1\Sigma q}, \; I_{1\Sigma d} = I_{sd} - \Delta I_{ir.d}, \\ &I_{1\Sigma q} = I_{sq} - \Delta I_{ir.q}, \end{aligned}\right\}, \qquad (7)$$

where $\Delta I_{1\Sigma d}$ and $\Delta I_{1\Sigma q}$ – are the longitudinal and transverse projections of the generalized vector $\bar{I}_{1\Sigma}$, respectively. According to the last relationship from formula (1), the values of the increments $\Delta I_{ir.d}$ and $\Delta I_{ir.q}$ of the stator current vector $\bar{I}_{1\Sigma}$ have not physically influence on the electromagnetic power P_{em}, which is transmitted through the SPMSM air gap. Consequently, these increments $\Delta I_{ir.d}$ and $\Delta I_{ir.q}$ also have not influence on the additional power losses ΔP_{ad} of the motor, which is part of the power P_{em}.

Therefore, in order to increase the precision of determination of the instantaneous additional power losses ΔP_{ad} f-r SPMSM, we will calculate them (in contrast to the relations from (1), known in publications [3 – 5]) differently by a way, excluding the mentioned increments $\Delta I_{ir.d}$ and $\Delta I_{ir.q}$ from the module I_s of the generalized stator current vector. Namely, we will find the additional losses ΔP_{ad} directly

proportional to the second degree of the modulus $I_{1\Sigma}$ of the stator current from the following mathematical expressions:

$$\left.\begin{aligned}\Delta P_{\text{ad}} &= R^{*}_{\text{ad}}\cdot\omega_{\text{s}}^{2}\cdot I_{1\Sigma}^{2}=R^{*}_{\text{ad}}\cdot\omega_{\text{s}}^{2}\cdot\left(I_{1\Sigma\text{d}}^{2}+I_{1\Sigma\text{q}}^{2}\right),\\ R^{*}_{\text{ad}} &= \frac{\Delta P_{\text{ad.n}}}{I_{1\Sigma\text{d.n}}^{2}+I_{1\Sigma\text{q.n}}^{2}}=\frac{\Delta P_{\text{ad.n}}}{I_{1\Sigma\text{.n}}^{2}}=R_{\text{ad}}\cdot\left(\frac{I_{\text{sn}}}{I_{1\Sigma\text{.n}}}\right)^{2}\end{aligned}\right\} \quad (8)$$

through the instantaneous values of the mentioned modulus $I_{1\Sigma}$ or longitudinal $I_{1\Sigma.\text{d}}$ and transverse $I_{1\Sigma.\text{q}}$ projections of the generalized vector $\bar{I}_{1\Sigma}$ on the axes of the rotating OCS «d – q». In formula (8): R^{*}_{ad} – is the refined value of the equivalent (intended for calculation of the additional power losses) motor active resistance, which is calculated through the nominal (that is corresponding to the nominal SPMSM mode) values of: the additional power losses $\Delta P_{\text{ad.n}}$, as well as the module $I_{1\Sigma.\text{n}}$, longitudinal $I_{1\Sigma\text{d.n}}$ and transverse $I_{1\Sigma\text{q.n}}$ projections of the motor stator current vector $\bar{I}_{1\Sigma.\text{n}}$.

In order to find the increment $\Delta I_{\text{q.ad}}$ of the transverse projection of the generalized stator current vector $\bar{I}_{\text{s}}$ (caused in SPMSM by the transmission of additional power losses ΔP_{ad} through the air gap of the motor), we shall make the energy balance for the electromagnetic power P_{em} of this motor, taking into consideration (8) and the last relation from formula (1):

$$P_{\text{em}}=\omega_{\text{s}}\cdot T_{\text{em}}=\omega_{\text{s}}\cdot\left(T+\Delta T_{\text{mech}}\right)+R^{*}_{\text{ad}}\cdot\omega_{\text{s}}^{2}\cdot I_{1\Sigma}^{2}. \quad (9)$$

Substituting into expression (9) the known relations for determining the electromagnetic T_{em} and rotating $(T+\Delta T_{\text{mech}})$ moments in [1, 5]:

$$T_{\text{em}}=\Phi_{\text{md}}I_{1\Sigma\text{q}} \quad \text{and} \quad T+\Delta T_{\text{mech}}=\Phi_{\text{md}}I_{1\text{q}}, \quad (10)$$

we obtain, taking into account the relation

$$I_{1\Sigma\,\text{q}}^{2}=\left(I_{1\text{q}}+\Delta I_{\text{ad.q}}\right)^{2}=I_{1\text{q}}^{2}+2I_{1\text{q}}\cdot\Delta I_{\text{ad.q}}+\Delta I_{\text{ad.q}}^{2}, \quad (11)$$

the following equation:

$$\omega_{\text{s}}\cdot\Phi_{\text{md}}\cdot\left(I_{1\Sigma\,\text{q}}-I_{1\text{q}}\right)=R^{*}_{\text{ad}}\cdot\omega_{\text{s}}^{2}\cdot\left(I_{1\Sigma\,\text{d}}^{2}+I_{1\Sigma\,\text{q}}^{2}\right). \quad (12)$$

Reducing the left and right parts by the multiplier ω_{S} and denoting the difference $(I_{1\Sigma\text{q}}-I_{1\text{q}})$ between the transverse projections $I_{1\Sigma\text{q}}$ and $I_{1\text{q}}$ as the increment $\Delta I_{\text{ad.q}}$ of the transverse projection I_{sq} of the generalized motor stator current vector $\bar{I}_{\text{s}}$ caused by transporting the additional power losses ΔP_{ad} through the air gap SPMSM, we transform equation (12) to the form of

$$\Delta I_{\text{ad.q}}^{2}+\Delta I_{\text{ad.q}}\cdot\left(2I_{1\text{q}}-\frac{\Phi_{\text{md}}}{|\omega_{\text{s}}|R^{*}_{\text{ad}}}\right)+I_{1\Sigma\,\text{d}}^{2}+I_{1\text{q}}^{2}, \quad (13)$$

where the unknown variable value is the increment $\Delta I_{\text{ad.q}}$.

The solution of the quadratic algebraic equation (13) is an analytic relationship:

$$\Delta I_{\text{ad.q}}=\left(\frac{0.5\Phi_{\text{md}}}{|\omega_{\text{s}}|\cdot R^{*}_{\text{ad}}}-I_{1\text{q}}\right)-\left[\left(\frac{0.5\Phi_{\text{md}}}{|\omega_{\text{s}}|\cdot R^{*}_{\text{ad}}}-I_{1\text{q}}\right)^{2}-I_{1\Sigma\,\text{d}}^{2}-I_{1\text{q}}^{2}\right]^{2}, \text{ where } I_{1\Sigma\,\text{d}}=I_{1\text{d}}. \quad (14)$$

From the analysis of dependence (14) it is revealed that as the frequency ω_{S} of the stator (equal to the speed ω of the rotor) approaches zero, then the increment $\Delta I_{\text{ad.q}}$ tends to zero.

To create instantaneous values of longitudinal projection Φ_{md} of magnetic flux and rotating torque $(T+\Delta T_{\text{mech}})$ SPMSM at a given angular frequency $\omega_{\text{S}}=\omega$ of the motor stator or rotor, the specific values are required of: longitudinal $I_{1\text{d}}$ and transverse $I_{1\text{q}}$ projections and module I_1 of the generalized stator current vector $\bar{I}_1$ (which correspond to the idealized representation of SPMSM), as well as refined (corresponding to the real representation of this motor) values of module I_{S} and orthogonal projections I_{sd} and I_{sq} of the generalized stator current vector $\bar{I}_{\text{s}}$ SPMSM. The values of the above quantities are determined from formulas (2), (6) and (14) by means of the following analytical dependencies:

$$\left.\begin{aligned}&I_{1\text{d}}=\left(\Phi_{\text{md}}-\Psi_{\text{f}}\right)/L_{\text{m}},\ I_{1\text{q}}=\left(T+\Delta T_{\text{mech}}\right)/\Phi_{\text{md}},\\ &I_1=\sqrt{I_{1\text{d}}^{2}+I_{1\text{q}}^{2}},\ \bar{I}_1=I_{1\text{d}}+jI_{1\text{q}},\\ &I_{\text{sd}}=I_{1\text{d}}+\Delta I_{\text{ir.d}},\ \ I_{\text{sq}}=I_{1\text{q}}+\Delta I_{\text{ir.q}}+\Delta I_{\text{ad.q}},\\ &I_{\text{s}}=\sqrt{\left(I_{1\text{d}}+\Delta I_{\text{ir.d}}\right)^{2}+\left(I_{1\text{q}}+\Delta I_{\text{ir.q}}+\Delta I_{\text{ad.q}}\right)^{2}},\\ &\bar{I}_{\text{s}}=\left(I_{1\text{d}}+\Delta I_{\text{ir.d}}\right)+j\left(I_{1\text{q}}+\Delta I_{\text{ir.q}}+\Delta I_{\text{ad.q}}\right).\end{aligned}\right\} \quad (15)$$

IV. RESEARCH MATERIALS

In steady operation modes of the SPMSM (with parameters from [11] and nominal values of useful power 35.2kW and speed 2800rpm) the electromag-netic and energy processes of this motor were calculated. The mentioned calculations were carried out for different instantaneous values of speed and load, using the obtained refined calculated analytical dependences: for the first (at speeds $|n|\le n_{\text{n}}$ and at null longitudinal projection $I_{1\text{d}}=0$ of stator current) and for the second (at speeds $|n|>n_{\text{n}}$, and at negative projection $I_{1\text{d}}<0$ of stator current) zones of speeds. In the second zone, the choice of values of projections $I_{1\text{d}}$ and $I_{1\text{q}}$ of stator current corresponded to minimization of the stator voltage modulus ($U_{\text{s}}=\min$) SPMSM [12].

Results of refined calculations of electromagnetic processes and power characteristics of the researched motor are presented in Table I, Table II and Table III. Also in Table II and Table III there are additionally calculated ratios $\Delta P_{\text{em}}/\Delta P^{*}_{\text{em}}$ between inaccurately determined (without taking into account components of electric power losses, caused by transportation of magnetic and additional power losses to the magnetizing circuit and through the SPMSM air

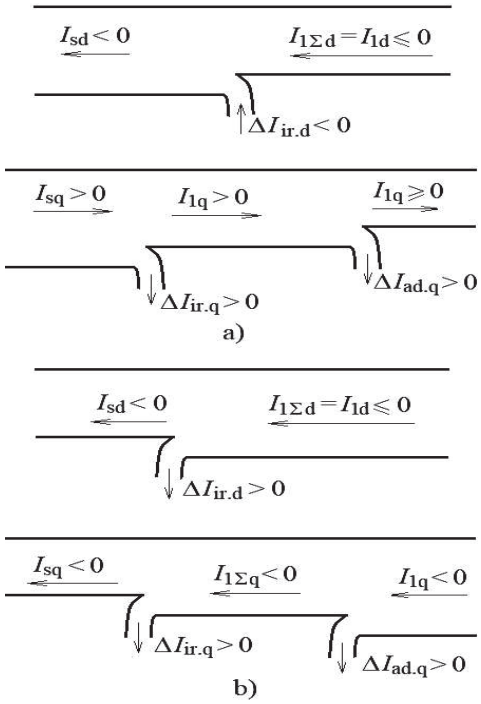

Fig. 2. Diagram of distribution of increments $\Delta I_{ir.d}$, $\Delta I_{ir.q}$ and $\Delta I_{ad.q}$ of stator current between projections I_{sd}, $I_{1\Sigma d}$, I_{1d} and I_{sq}, $I_{1\Sigma q}$, I_{1q} of generalized stator current vectors $\bar{I}_s$, $\bar{I}_{1\Sigma}$, $\bar{I}_1$ in f-r SPMSM for motor (a) and generator (b) modes of its operation

gap respectively) electromagnetic power losses ΔP_{em} and refined calculated electromagnetic power losses ΔP^*_{em}. The mentioned electromagnetic losses ΔP_{em} and the included to them electrical power losses ΔP_e were determined inaccurately from the ratios:

$$\Delta P_{em} = \Delta P_e + \Delta P_{ir} + \Delta P_{ad} \quad \text{and} \quad \Delta P_e = R_s \cdot I_1^2 . \quad (16)$$

According to the calculated ratio $\Delta P_{em}/\Delta P^*_{em}$, given in Table II for the first speed zone, the difference between inaccurate ΔP_{em} and refined ΔP^*_{em} values of the main electromagnetic power losses f-r SPMSM varies from 2.3% (at nominal speed equal to 2800rpm) to 1.5% (at speed 300rpm). And between the above mentioned electromagnetic power losses the following ratios are always fulfilled: $\Delta P^*_{em} > \Delta P_{em}$ – for propulsion or vice versa $\Delta P^*_{em} < \Delta P_{em}$ – for generator mode of SPMSM operation. According to Table II and Table III, the calculated relationships I_s/I_1 between the modules I_s and I_1 of the generalized vectors of the stator current $\bar{I}_s$ and $\bar{I}_1$ SPMSM take values from 0.9696 to 1.0317 (always values greater, than one, correspond to the motor mode of operation and values less, than one, correspond to the generator mode of operation of this motor).

From formulus (7) and (15) the analytical dependences were obtained for SPMSM, which are tied mathematically increments $\Delta I_{ir.d}$, $\Delta I_{ir.q}$ and $\Delta I_{ad.q}$ with the orthogonal projections I_{1d} and I_{1q}, $I_{1\Sigma d}$ and $I_{1\Sigma q}$, I_{sd} and I_{sq} of the generalized vectors $\bar{I}_1$, $\bar{I}_{1\Sigma}$ and $\bar{I}_s$ stator current, respectively. Taking into account the given calculation data in Table II and Table III, let us draw up in Fig. 2 a diagram of the distribution of above mentioned increments of currents in the f-r SPMSM for the motor and generator modes of its operation.

From the analysis of Tables II and III it follows that at the values of useful torque T in the range of speeds equal and higher than the nominal speed: $|n| \geq n_n$, – it is required to provide for normal functioning SPMSM a stator supply voltage reserve, which is equaled to (16 – 26)% of the nominal stator voltage of the motor.

V. Conclusions

New analytical dependences (5) – (7), (14) and (15) for determining the increments of longitudinal and transverse projections of the f-r SPMSM stator current (caused by transportation of magnetic and additional power losses to the magnetizing circuit or through the air gap of the motor, respectively) have been obtained. On the basis of these dependencies, in steady modes of operation of this motor we have performed refined calculations of its: stator current, main electromagnetic power losses, main consumed active power, efficiency and power factor for the first and second speed zones, – at the different values of speed and load. Peculiarities of steady modes of the researched SPMSM are revealed and the diagram of distribution of the mentioned increments of the projections of the motor stator current is constructed.

Abstract*—The research is devoted to synthesize a controller with a fractional-order integral component to achieve the order of astaticism of the closed-loop speed BLDCM higher than 1 and with a neural network to improve the static and dynamic control accuracy. The control object is identified by a fractional-order differential equation. Four types of controllers are synthesized: a classic PID to provide settings close to the modular optimum (IntPID); a controller with a fractional-integral component that provides the order of astaticism of the loop 1.8 (FrPID), and – what is the scientific novelty of the work – hybrid controllers based on the first two, supplemented by neural networks of direct signal propagation NN–IntPID, NN–FrPID. FrPID compared to IntPID allowed to reduce the mean square error by almost 5 times, and the neural controller with a fractional integral component provided the best results: overshoot with a jump in the reference signal was reduced from 2.98% to 0.35%, the mean square error with a linearly changing reference signal was reduced by 11 times and the relative speed error decreases from 0.00801 to 0.00022, more than 35 times. The proposed algorithm for fast learning in each cycle of the control program also ensures the adaptation of the controller when the parameters of the control object change, what makes the possibility of using neural controllers with a fractional integral component for other objects, such as universal collector motors, electromagnetic brakes with adjustable torque.

Keywords—*BLDCM, PID-regulator, hybrid Neural Network – PI$^{\mu}$D-controller, astaticism of the closed-loop system, fast learning algorithm.*

I. Introduction

Brushless DC motors (BLDCM) have become increasingly widespread in recent decades due to the fact that the production of these motors saves resources – there are no windings in the rotor, the stator uses 30-40% less copper than in asynchronous motors, the manufacturing technology is simpler, the cost of motors is 4 times less. However, nonlinear dependencies between the current and the magnetic field strength due to the saturation of the magnetic system complicate the control of BLDCM. To synthesize a speed controller, instead of a full nonlinear model of such a motor, it is advisable to use differential equations with a fractional order, since they belong to the class of linear equations, which allows the use of methods for solving classical problems of automatic control theory [1], [2], and the emergence of approximation methods for calculating a fractional integral makes it possible to use controllers with such components in modern microprocessor control systems [3]–[6].

One of the most popular types of controllers – PID – using differential and integral components of fractional order $\left(PI^{\mu}D^{\nu}\right)$ allows to obtain a controller that is more flexible in tuning, while improving the quality indicators of transient and steady-state processes [7]–[10], its transfer function looks like this:

$$H_r(s)=\frac{Y_r(s)}{X(s)}=k_{rp}+k_{ri}\frac{1}{s^{\mu}}+k_{rd}s^{\nu}, \quad (1)$$

If it is possible to accept $\nu=1-\mu$, then the transfer function of the controller can be written in the following form:

$$H_r(s)=\frac{Y_r(s)}{X(s)}=k_{rp}+\frac{1}{s^{\mu}}\left(k_{ri}+k_{rd}s\right), \quad (2)$$

which can significantly simplify the calculation of the output signal of the controller.

And the main objective of this work is the synthesis of neural controllers as a combination *PID*, $PI^{\mu}D^{\nu}$ and artificial neural networks to achieve the following goal.

The goal of the work is the synthesis of a controller that includes an integral component of fractional order to obtain the order of astaticism of the closed speed BLDCM loop higher than 1, and an artificial neural networks of direct signal propagation to improve the static and dynamic control accuracy.

II. Identification of the Control Object

The transient processes of the BLDCM start-up when applying voltage surges of different amplitudes, calculated using the detailed model in Matlab speed_control_of_bldc_motor.slx, are characterized by a fast initial section and a delayed end of the transient process,

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

which is typical for solutions of differential equations of fractional order.

The BLDCM model, which provides sufficient accuracy, can be described in proportional units by the following transfer function:

$$H_{BLDC}(s)=\frac{\omega(s)/\omega_0}{U_c^*(s)}=\frac{1}{T_tT_as^{1+\mu}+T_ts^{\mu}+1}. \quad (3)$$

Then, taking into account the uncompensated time constant of the control system T_v and the gain of the power converter k_c, the control object is described as follows:

$$H_C(s)=\frac{1}{T_tT_as^{1+\mu}+T_ts^{\mu}+1}\frac{k_c}{T_vs+1}. \quad (4)$$

The parameters of such a BLDCM model were obtained during the start-up process with a jump of U_{ref} from $0.2U_n$ to U_n:

$$\begin{aligned}\mu&=0.851-0.045\omega_0^*,\\ T_a&=0.0031-0.0021\omega_0^*,\\ T_t&=0.0056+0.0091\omega_0^*.\end{aligned} \quad (5)$$

Table I shows the accuracy indicators of the obtained model.

TABLE I. ROOT MEAN SQURE ERROR OF BLDCM START PROCESS IDENTIFICATION WHEN CHANGING SPEED REFERENCE

ω_0^*	0.2	0.3	0.4	0.5	0.6
RMSE	0.019	0.020	0.018	0.017	0.015
ω_0^*	0.7	0.8	0.9	1.0	
RMSE	0.013	0.012	0.011	0.013	

These results allow us to consider the obtained model as a base for the synthesis of speed controllers with different internal architectures.

III. SYNTHESIS OF LINEAR REGULATORS

We will consider several variants of regulators, comparing static and dynamic indicators when processing tachograms, including jumps and linearly changing reference signals.

A number of assumptions were made during the modeling: the supply voltage limit is set significantly higher than the nominal one so that the regulators operate mainly in the active mode, and not in the saturation mode. The engine speed is calculated in proportional units, the step $\Delta t = 6.564\text{e-}05\text{s}$ is determined automatically and is assumed to be the same in all the graphs below, the relative time $t/\Delta t$ is displayed on the abscissa axes.

The solution of fractional differential equations describing the object is based on the transfer function (3), which allows only one calculation of the fractional integral of the order μ using the Oustaloup expansion [4]:

$$I^{\mu}(s)=\prod_{i=-N}^{N}\sqrt{\frac{\omega_{k\,i}{}^2+1}{\omega_{kp\,i}{}^2+1}}\frac{s+\omega_{kp\,i}}{s+\omega_{k\,i}}, \quad (6)$$

where $\omega_L=0.1^{3.75}s^{-1}$, $\omega_H=10^{3.75}s^{-1}$, $\lambda=\frac{\omega_H}{\omega_L}$, $N=8$, $\omega_{kp\,i}=\lambda^{\omega_L(i+N-0.5\mu)/(2N+1)}$, $\omega_{k\,i}=\lambda^{\omega_L(i+N+0.5\mu)/(2N+1)}$.

1. Considering $\mu\approx 1$, we synthesize a controller for tuning the speed loop to the modular optimum. For this, the tuned open loop, including the controller and the control object, must be described by the following transfer function:

$$H_{opt}(s)=\frac{1}{aT_vs}\frac{1}{T_vs+1},\ a=2. \quad (7)$$

Then we get a PID controller with parameters:

$$k_{rp}=\frac{T_t}{ak_cT_v},\ k_{ri}=\frac{1}{ak_cT_v},\ k_{rd}=\frac{T_aT_t}{ak_cT_v}. \quad (8)$$

Let us denote such a controller as IntPID. Considering that it includes an integrating link, when covered by single negative feedback we obtain an astatic system of the 1st order.

2. For an object that includes a unit of fractional-order μ, it is possible to synthesize a controller that ensures the order of astaticism $1+\mu$ with a transfer function of the tuned open circuit of the following form:

$$H_{opt}^{1+\mu}(s)=\frac{bT_vs+1}{abT_v^{\mu+1}s^{\mu+1}}\frac{1}{T_vs+1},\ 1<\mu+1<2,\ b>1. \quad (9)$$

The synthesis procedure consists of selecting parameters a,b depending on the order of astaticism [7]:

$$\begin{aligned}&(ab)\approx e^{-10.27+7.831(\mu+1)}\ \Rightarrow\\ &b\approx 7.336+0.792(ab)+3.83\ln(ab)\ \Rightarrow\\ &a=\frac{(ab)}{b}.\end{aligned} \quad (10)$$

Then, taking into account (4), we obtain $PI-PI^{\mu}D-regulator$:

$$\begin{aligned}&H_{PI-PI^{\mu}D}(s)=H_{opt}^{1+\mu}(s)/H_C(s)=\\ &=\left(1+\frac{1}{bT_vs}\right)\left(\frac{T_aT_ts}{aT_v^{\mu}k_c}+\frac{T_t}{k_caT_v^{\mu}}+\frac{1}{k_caT_v^{\mu}s^{\mu}}\right).\end{aligned} \quad (11)$$

Let us designate such a controller as FrPID.

A remarkable feature of the synthesized controller is that it gives the system an astatic order greater than 1 with stability reserves no less than when tuning to the modular optimum. This ensures lower oscillations and the absence of not only static but also speed errors.

As a result of modeling the system, graphs of transient processes were obtained for a jump (Fig. 1, a) and a linearly changing reference signal (Fig. 1, b). Visually, the graphs are

almost identical for both controllers. However, the overshoot for a jump in the reference signal with IntPID is 2.98%, and with FrPID – 0.61%, and for a linearly changing reference signal, it is clearly seen that the error graphs (Fig. 1, c) differ quite significantly, the root-mean-square error (RMSE) at the beginning of the transient process from point 1 to 10,000 and during the entire process from point 1 to 50,000 is almost 5 times less.

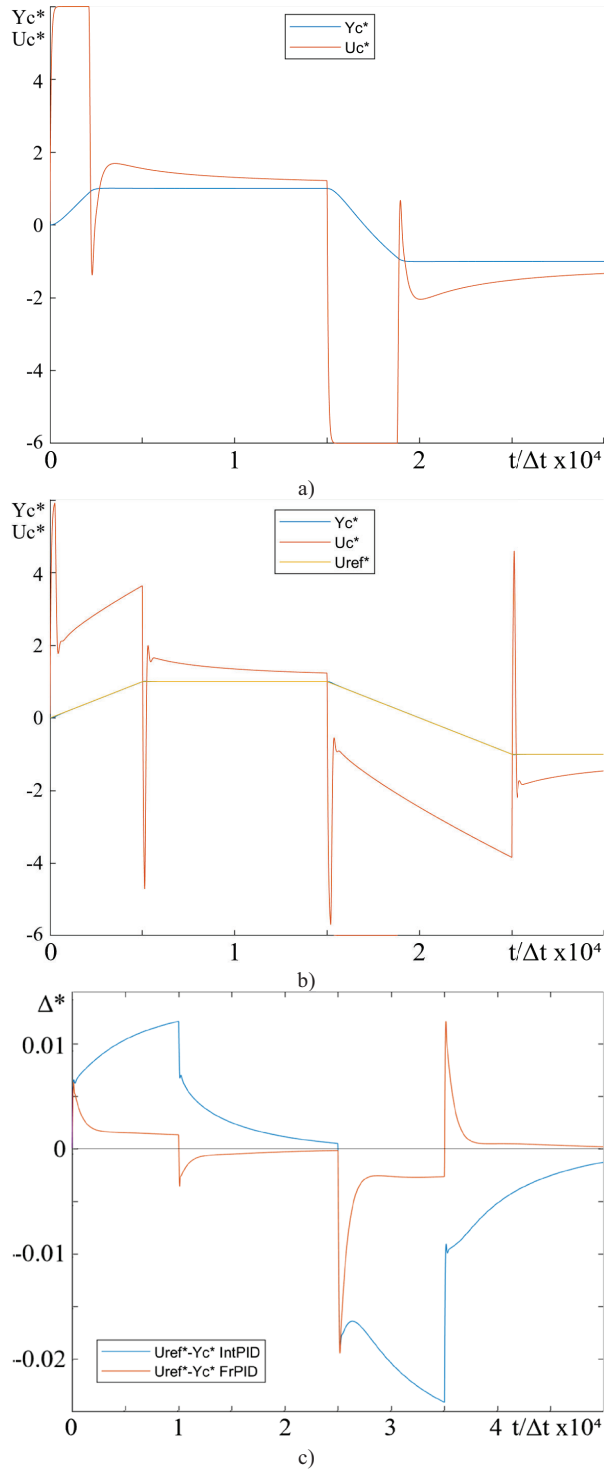

Fig. 1. Graphs of transient processes of the reference signal Uref*, converter voltage Uc*, speed Yc* with a jump (a) and linear change (b) of Uref and error (c) for case (b) when using linear regulators

III. Synthesis of Neuroregulators

Synthesized linear regulators allowed us to obtain fairly good results. However, modern technologies allow us to optimize the system performance by using adaptive regulators, among which neuroregulators [11]–[14] with a structure identical to the synthesized linear IntPID, FrPID seem to us to be the most promising. In such regulators, instead of amplifiers with fixed coefficients, fully connected neural networks of direct propagation with a small number of neurons are used (Fig. 2).

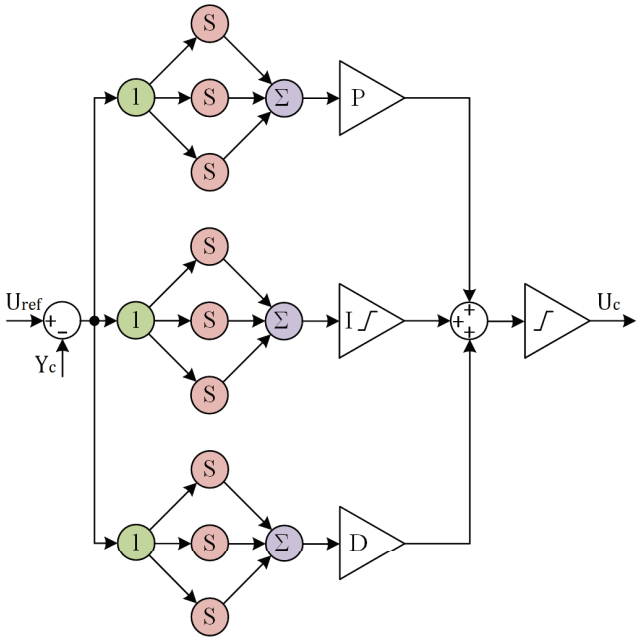

Fig. 2. Functional diagram of the neuro-PID controller

Let us designate such controllers as NN–IntPID, NN–FrPID, respectively.

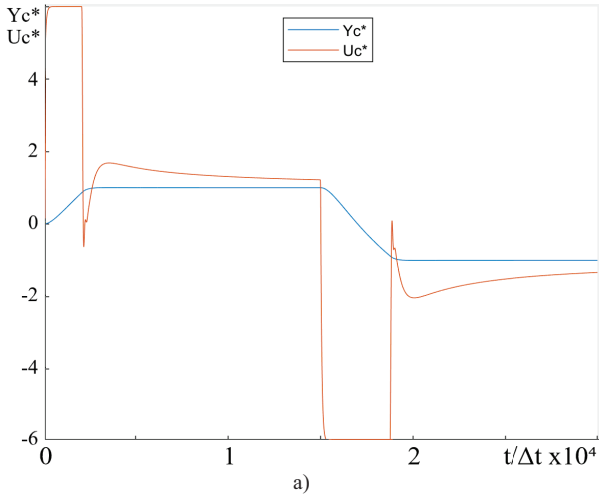
Neural networks in such controllers should contain one neuron in the input and output layers and 5…10 neurons in the hidden layer. If we use the hyperbolic tangent as activation functions $S(x)$, then they actually form a certain centrally symmetric nonlinear dependence between the error value and the output values of individual components. The output signal of such a neural network in a programming language containing matrix processing tools is calculated using a simple expression [14]:

$$y = S\left(S\left(x * w_2\right) * w_3\right), \tag{12}$$

where w_2; w_3 – matrix of dimension $[1,n]$; $[n,1]$ respectively, the operator "*" corresponds to the vector product of matrices.

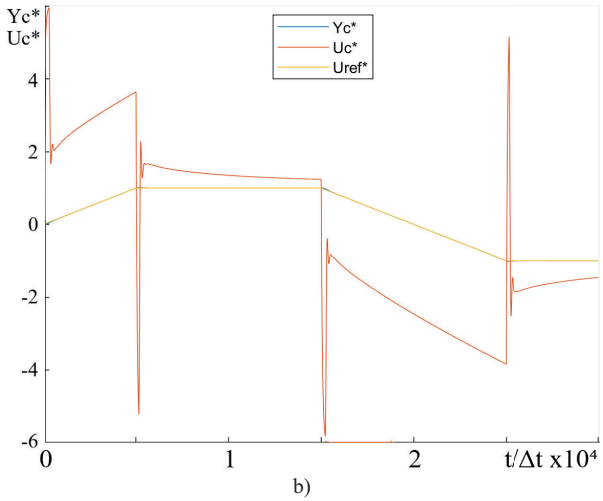
Traditionally, for training ANNs, the calculation of the RMSE on a certain interval is used, followed by correction of the weighting coefficients by the method of back propagation of the error using the Levenberg-Marquardt or gradient descent algorithms [15]–[17]. However, for the class of objects under consideration, a fast-learning algorithm can be applied in each cycle of the transient process calculation program.

For this purpose, using the model of the control object, in each cycle of calculating the controller output signal and the



model response, the error $e = Uref - Yc$ is calculated. Since the goal of control is to achieve an error equal to zero, it is its value that is used to correct the weighting coefficients using the Error Backpropagation method (EBP) in combination with the Scaled Conjugate Gradient (SCG) method. In turn, the SCG method is based on calculating the derivative of the activation function, which for the hyperbolic tangent is calculated using the expression $S'(x) \sim S(x)(1 - S(x))$ [13]. Then the calculation of the correction value of the weighting coefficients is carried out using the following procedure:

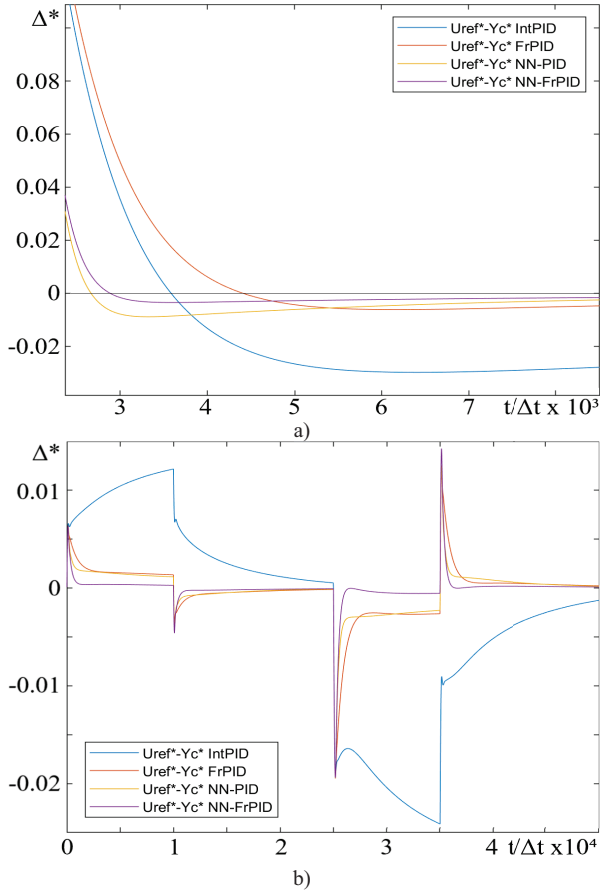
$$
\begin{aligned}
&\% \ EBP \ with \ Scaled \ Conjugate \ Gradient \\
&e = Uref - Yc; \\
&s2 = S(e * w2); \\
&sx2 = s2 .* (1 - s2); \\
&dE2 = ((e * w2) .* sx2) .* e; \\
&s3 = S(s2 * w3); \\
&sx3 = s3 .* (1 - s3); \\
&dE3 = (e .* sx3) .* (e * w2)'; \\
&w2 = w2 + alfa .* dE2; \\
&w3 = w3 + alfa .* dE3;
\end{aligned}
\tag{13}
$$



in which the learning coefficient α is set in the range from 0.1 to 1.0, the operator " * " corresponds to the vector product of matrices, " .* " – to element-wise multiplication, " ' " – to matrix transposition.

It is important to note that it is advisable to conduct training with a reference signal changing so that the controller does not enter the saturation mode and in the 1st quadrant, i.e. with a non-negative value of both the reference signal itself and its derivative. We chose a signal linearly increasing from 0 to 1 with a limitation and such a rate of increase that does not lead to saturation of the controller.

As a result of repeating this procedure for 100 epochs, the regulator is adjusted, which is then tested by applying a reference signal in a jump and linearly changing with different acceleration already in the range $-1...+1$ (Fig. 3).



a)

b)

Fig. 3. Response of trained systems with NN–IntPID and NN–FrPID to jumps (a) and linear changes (b) in the reference signal

Visually, the graphs do not differ significantly from Fig. 1, a, b. However, the overshoot during a jump in the reference signal with NN-IntPID is 0.89%, and with NN-FrPID – 0.35%, reaching the extremum with neuroregulators occurs almost twice as early as with linear regulators. The relative speed error c=Δ*/a* decreases from 0.00801 with IntPID and 0.00091 with FrPID to 0.00077 with NN-IntPID and by another 3.5 times to 0.00022 with NN-FrPID. Fig. 4 shows the graphs of the change in the error in transient processes when using different regulators, and Table II compares various indicators depending on the regulator type.

a)

b)

Fig. 4. Graphs of transient processes of errors with a jump in the reference (a) and a linearly changing reference (b) when using different regulators

TABLE II. COMPARATIVE INDICATORS OF INTPID, FRPID AND NN–INTPID, NN–FRPID

Regulator	RMSE		
	RMSE 1:10,000	RMSE 1:50,000	
IntPID	0.0102	0.0107	
FrPID	0.0021	0.0027

IntPID	0.0298	0.431	0.00801
FrPID	0.0061	0.430	0.00091
NN–IntPID	0.0089	0.213	0.00077
NN–FrPID	0.0035	0.235	0.00022

IV. CONCLUSION

Thus, based on the identification of the starting processes of a brushless DC motor by a fractional-order differential equation with an error of no more than 2%, it is shown that several different types of controllers can be used for such an object. The use of a classic PID controller allows for RMSE to be provided with a linear reference signal at the level of 0.010…0.012, but with an error increasing to 0.025 and a slowly decreasing static error, which is typical for fractional-aperiodic systems. A reduction of 5 or more times in the root-mean-square error, a rapid reduction in the static error to zero and an error to 0.002 with a linear change in the reference signal is provided by a controller with a fractional-order integral component, which also imparts to the system the property of astaticism for the reference and disturbance of order 1.8. Even higher control accuracy is achieved by combining a fractional-integral controller with fully connected three-level direct-propagation neural networks as preamplifiers of the fractional-integral and proportional components, which allows for both static and velocity errors in most of the transient process to be close to zero.

This result is also achieved due to two more factors: 1. Using a fast learning algorithm – in each cycle of the transient process calculation program – based only on the instantaneous error value and considering the goal of learning to reduce the error to zero; 2. Preliminary selection of the structure and coefficients of the controller, which allows for faster finding of the necessary weighting coefficients of the neurocontroller.

Taking into account the close description of both BLDCM and universal AC/DC motors with series excitation, electromagnetic brake with adjustable torque [7], the proposed approach to the synthesis of neurocontrollers can be used for all types of the listed devices. Verification of this, including experimental, can be the subject of further research.

***Abstract*—Multi-walled nanotube (MWN) nonlinear free oscillations are simulated by three nonlinear partial differential equations (NPDEs). Nonlinear oscillations of MWN are modeled by using the shell theory. Koiter-Sanders theory is applied to simulate geometrically nonlinear deformations of MWNs. The van der Waals nonlinearity and surface effects are accounted in MWN oscillations model.**

Three NPDEs are transformed to nonlinear ordinary differential equations (NODEs) by applying the Galerkin technique.

As follows from the NODEs analysis, the free nonlinear oscillations of MWN are nonlinear modes. Such nonlinear modes are essentially curvilinear. The properties on nonlinear modes are analyzed numerically.

Keywords— nonlinear oscillation of multi-walled shell, surface effect, van der Waals nonlinearity, nonlinear ordinary differential equation

I. Introduction

Most part of nano research is devoted to the use of beam models to study the nonlinear dynamics of MWNs. In this paper shell models are used to simulate the oscillations of MWN.

Mathematical model of plate is applied to simulate the oscillations of nanofilms. The surface layers, theory of geometrically nonlinear plate by von Karman are applied to describe the oscillations of nanofilms in [1, 2]. The shear theory of the first order and the surface effect are applied to analyze nanoplate forced vibrations in Ref. [3, 4].

Now it is considered the shell models of nanotube oscillations. The linear oscillations of nanotube are modeled using surface effect and shell theory in Ref. [5, 6]. The accounting of the surface effect has essential influence on the values of the nanotube eigenfrequencies. The buckling behavior of nanotube is studied in [7] using the shell nonlinear model. Effect of imperfections on nonlinear buckling of nanoshell is analyzed in Ref. [8]. Gurtin-Murdoch surface theory (GMST) is used in this study. Nanotube free oscillations with account of geometrical nonlinearity and surface effect are discussed in [9, 10] using the shell nonlinear theory. The double-walled nanostructure oscillations are studied accounting effect of surface on four surfaces and shell theory of Novozhilov in Ref. [11]. As follows from [12], the effect of surface has considerable influence on piezoelectric nanotube oscillations. The detailed discussion of surface effect is published in [13]. The influence of effect of surface on static buckling of nanotube is considered in [14, 15]. The survey of solid mechanics modeling of nanotubes is presented in [16].

In the present paper, the system of NPDEs is obtained to simulate the vibrations of nanoshell with account of nonlocal elasticity, effect of surface and geometrical nonlinear behavior. Using the Galerkin method, the obtained system of NPDEs is transformed into system of NODEs. Nonlinear normal oscillations modes, which are analyzed in the configuration space, are discovered by means of numerical simulation. As follows from the results on simulations, nonlinear oscillations modes are essentially curvilinear.

II. Problem Formulation and Main Equations

The nanotube with N walls is described by N thin shells, which are linked by van der Waals forces. These forces are essentially nonlinear. N walled nanotube has the same thickness of all walls h and the i^{th} wall has the radius R_i. Nanotube performs oscillations with moderate amplitudes. In this case, the nanotube geometrical nonlinear behavior is considered.

MWN is analyzed in cylindrical coordinates (x, θ, z). The main unknowns of the problem are i^{th} wall projections of the displacements on the cylindrical coordinates u_i, v_i, w_i. A rotary inertia and a shear are not considered in the shell models. The displacements projections of arbitrary points of i^{th} wall $u_x^{(i)}, u_\theta^{(i)}, u_z^{(i)}$ are

$$\begin{bmatrix} u_x^{(i)} \\ u_\theta^{(i)} \\ u_z^{(i)} \end{bmatrix} = \begin{bmatrix} u_i \\ v_i \\ w_i \end{bmatrix} - z \begin{bmatrix} w_{i,x} \\ \dfrac{w_{i,\theta}}{R_i} - \dfrac{v_i}{R_i} \\ 0 \end{bmatrix}. \tag{1}$$

Three kinds of nonlinearity are considered here. The geometrical nonlinearity is the first kind. The van der Waals loads between nanotube walls are the second kind of

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

nonlinearity. The axis stresses resultants are nonlinear functions of displacements, which are used in boundary conditions. This stresses resultants generate the third type of nonlinearity.

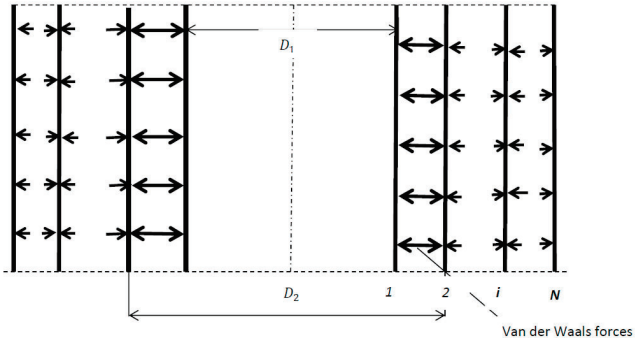

Fig. 1. *N*-walled nanotube

Sanders-Koiter theory, which is modeled the geometrical nonlinear behavior of the nanoshell, is described by the equations [17]:

$$\begin{bmatrix}\varepsilon_{xx}^{(i)}\\ \varepsilon_{\theta\theta}^{(i)}\\ \gamma_{x\theta}^{(i)}\end{bmatrix}=\begin{bmatrix}\varepsilon_{x,0}^{(i)}\\ \varepsilon_{\theta,0}^{(i)}\\ \gamma_{x\theta,0}^{(i)}\end{bmatrix}+z\begin{bmatrix}k_x^{(i)}\\ k_\theta^{(i)}\\ k_{x\theta}^{(i)}\end{bmatrix}=\begin{bmatrix}u_{i,x}+\varepsilon_{i,X,0}^{(NL)}\\ \frac{v_{i,\theta}}{R_i}+\frac{w_i}{R_i}+\varepsilon_{i,\theta,0}^{(NL)}\\ \frac{u_{i,\theta}}{R_i}+v_{i,x}+\gamma_{i,X\theta,0}^{(NL)}\end{bmatrix}$$
$$+z\begin{bmatrix}-w_{i,xx}\\ \frac{v_{i,\theta}}{R_i^2}-\frac{w_{i,\theta\theta}}{R_i^2}\\ -\frac{2w_{i,x\theta}}{R_i}+\frac{3v_{i,x}}{2R_i}-\frac{u_{i,\theta}}{2R_i^2}\end{bmatrix}, \quad (2)$$

where

$$\varepsilon_{i,X,0}^{(NL)}=\frac{1}{2}\left(w_{i,x}\right)^2+\frac{1}{8}\left(v_{i,x}-\frac{u_{i,\theta}}{R_i}\right)^2;$$
$$\varepsilon_{i,\theta,0}^{(NL)}=\frac{1}{2}\left(\frac{w_{i,\theta}}{R_i}-\frac{v_i}{R_i}\right)^2+\frac{1}{8}\left(\frac{u_{i,\theta}}{R_i}-v_{i,x}\right)^2;$$
$$\gamma_{i,X\theta,0}^{(NL)}=w_{i,x}\left(\frac{w_{i,\theta}}{R_i}-\frac{v_i}{R_i}\right);$$

$\varepsilon_{x,0}^{(i)},\varepsilon_{\theta,0}^{(i)},\gamma_{x\theta,0}^{(i)}$ are middle surfaces strains.

The nonlocal Hooke's law describes the elastic properties of the i^{th} wall of nanotube

$$\sigma_{xx}^{(i)}-l^2\nabla^2\sigma_{xx}^{(i)}=(\lambda+2\mu)\varepsilon_{xx}^{(i)}+\lambda\varepsilon_{\theta\theta}^{(i)}; \quad (3)$$
$$\sigma_{\theta\theta}^{(i)}-l^2\nabla^2\sigma_{\theta\theta}^{(i)}=(\lambda+2\mu)\varepsilon_{\theta\theta}^{(i)}+\lambda\varepsilon_{xx}^{(i)};$$
$$\sigma_{x\theta}^{(i)}-l^2\nabla^2\sigma_{x\theta}^{(i)}=\mu\gamma_{x\theta}^{(i)},$$

where $\nabla^2(\cdot)=\frac{\partial^2(\cdot)}{\partial x^2}+\frac{\partial^2(\cdot)}{R_i^2\partial\theta^2}$; $\sigma_{xx}^{(i)},\sigma_{\theta\theta}^{(i)},\sigma_{x\theta}^{(i)}$ are stress tensor elements; μ,λ are parameters of Lame; $l=e_0a$ is the scale coefficient.

According to GMST [18], the constitutive equations for infinitesimal surface layers is the following

$$\sigma_{\alpha\beta}^{(i,s)}=\tau_i^{(s)}\delta_{\alpha\beta}+\left(\tau_i^{(s)}+\lambda^{(s)}\right)\varepsilon_{\gamma\gamma}^{(i,s)}\delta_{\alpha\beta}+$$
$$2\left(\mu^{(s)}-\tau_i^{(s)}\right)\varepsilon_{\alpha\beta}^{(i,s)}+\tau_i^{(s)}u_{\alpha,\beta}^{(i,s)}, \quad (4)$$
$$\sigma_{\alpha z}^{(i,s)}=\tau_i^{(s)}u_{z,\alpha}^{(i,s)}, \quad (5)$$

where $\delta_{\alpha\beta}$ is Kronecker delta; $\lambda^{(s)},\mu^{(s)}$ are surface parameters of Lame; $\tau_i^{(s)}$ are values of residual stresses.

The surface stresses satisfy the following equations:

$$\sigma_{xx}^{(i,s)}=\tau_i^{(s)}+\left(\lambda^{(s)}+2\mu^{(s)}\right)\varepsilon_{xx}^{(i,s)}+\left(\tau_i^{(s)}+\lambda^{(s)}\right)\varepsilon_{\theta\theta}^{(i,s)}$$
$$-\tau_i^{(s)}\varepsilon_{i,X,0}^{(NL)}; \quad (6)$$
$$\sigma_{\theta\theta}^{(i,s)}=\tau_i^{(s)}+\left(\tau_i^{(s)}+\lambda^{(s)}\right)\varepsilon_{xx}^{(i,s)}+\left(\lambda^{(s)}+2\mu^{(s)}\right)\varepsilon_{\theta\theta}^{(i,s)}$$
$$-\tau_i^{(s)}\left(\frac{w_i}{R_i}+\varepsilon_{i,\theta,0}^{(NL)}\right);$$
$$\sigma_{x\theta}^{(i,s)}=\mu^{(s)}\gamma_{x\theta}^{(i,s)}-\tau_i^{(s)}\left[\left[\frac{\partial v_i}{\partial x}+\gamma_{i,X\theta,0}^{(NL)}\right.\right.$$
$$\left.\left.+z\left\{-\frac{w_{i,x\theta}}{R_i}+\frac{3v_{i,x}}{2R_i}-\frac{u_{i,\theta}}{2R_i^2}\right\}\right]\right];$$
$$\sigma_{\theta x}^{(i,s)}=\mu^{(s)}\gamma_{x\theta}^{(i,s)}-\tau_i^{(s)}\left[\left[\frac{u_{i,\theta}}{R_i}+\gamma_{i,X\theta,0}^{(NL)}\right.\right.$$
$$\left.\left.+z\left\{-\frac{w_{i,x\theta}}{R_i}+\frac{v_{i,x}}{2R_i}-\frac{u_{i,\theta}}{2R_i^2}\right\}\right]\right].$$

Following the paper [19], the stresses σ_{zz} satisfy the following equation:

$$\sigma_{zz}^{(i)}=\frac{2z}{h}\left[\tau_i^{(s)}\nabla^2w_i-\rho^{(s)}\ddot{w}_i\right], \quad (7)$$

where $\ddot{w}_i=\frac{\partial^2w_i}{\partial t^2}$; $\rho^{(s)}$ is surface density.

The i^{th} wall nanotube potential energy $\Pi^{(i)}$ is the following:

$$\Pi^{(i)}=\frac{1}{2}\int_{S_i}\int_{-h/2}^{h/2}\left(\sigma_{xx}^{(i)}\varepsilon_{xx}^{(i)}+\sigma_{\theta\theta}^{(i)}\varepsilon_{\theta\theta}^{(i)}+\sigma_{x\theta}^{(i)}\gamma_{x\theta}^{(i)}\right)dzdxR_id\theta+$$
$$\frac{1}{2}\int_{S_i^+}\left(\sigma_{xx}^{(i,+)}\varepsilon_{xx}^{(i,+)}+\sigma_{\theta\theta}^{(i,+)}\varepsilon_{\theta\theta}^{(i,+)}+\sigma_{xz}^{(i,+)}\gamma_{xz}^{(i,+)}+\sigma_{yz}^{(i,+)}\gamma_{yz}^{(i,+)}\right.$$
$$\left.+0.5\sigma_{x\theta}^{(i,+)}\gamma_{x\theta}^{(i,+)}+0.5\sigma_{\theta x}^{(i,+)}\gamma_{x\theta}^{(i,+)}\right)dxR_id\theta$$
$$\frac{1}{2}\int_{S_i^-}\left(\sigma_{xx}^{(i,-)}\varepsilon_{xx}^{(i,-)}+\sigma_{\theta\theta}^{(i,-)}\varepsilon_{\theta\theta}^{(i,-)}+\sigma_{xz}^{(i,-)}\gamma_{xz}^{(i,-)}+\sigma_{yz}^{(i,-)}\gamma_{yz}^{(i,-)}\right.$$
$$\left.+0.5\sigma_{x\theta}^{(i,-)}\gamma_{x\theta}^{(i,-)}+0.5\sigma_{\theta x}^{(i,-)}\gamma_{x\theta}^{(i,-)}\right)dxR_id\theta, \quad (8)$$

where $\sigma_{xx}^{(i,\mp)},\sigma_{\theta\theta}^{(i,\mp)},\sigma_{xz}^{(i,\mp)},\sigma_{yz}^{(i,\mp)},\sigma_{x\theta}^{(i,\mp)},\sigma_{\theta x}^{(i,\mp)}$ are components of stresses for inside and outside surfaces; S_i is domain of middle surface of i^{th} layer.

The i^{th} layer potential energy has the following form:

$$\Pi^{(i)}=\frac{1}{2}\int_{S_i}\left(\bar{N}_{xx}^{(i)}\varepsilon_{x,0}^{(i)}+\bar{M}_{xx}^{(i)}k_x^{(i)}+\bar{N}_{\theta\theta}^{(i)}\varepsilon_{\theta,0}^{(i)}+\bar{M}_{\theta\theta}^{(i)}k_\theta^{(i)}+\right.$$
$$\left.\bar{N}_{x\theta}^{(i)}\gamma_{x\theta,0}^{(i)}+\bar{M}_{x\theta}^{(i)}k_{x\theta}^{(i)}+Q_x^{(i,s)}w_{i,x}+Q_y^{(i,s)}\frac{w_{i,\theta}}{R_i}\right)dxR_id\theta, \quad (9)$$

where

$$\bar{N}_{xx}^{(i)}=l^2\nabla^2N_{xx}^{(i)}+A_{11}^{(i)}\varepsilon_{x,0}^{(i)}+A_{12}^{(i)}\varepsilon_{\theta,0}^{(i)}+2\tau_i^{(s)}-2\tau_i^{(s)}\varepsilon_{i,X,0}^{(NL)};$$
$$\bar{N}_{\theta\theta}^{(i)}=l^2\nabla^2N_{\theta\theta}^{(i)}+A_{11}^{(i)}\varepsilon_{\theta,0}^{(i)}+A_{12}^{(i)}\varepsilon_{x,0}^{(i)}+2\tau_i^{(s)}$$
$$-2\tau_i^{(s)}\left(\frac{w_i}{R_i}+\varepsilon_{i,\theta,0}^{(NL)}\right); \quad (10)$$
$$\bar{N}_{x\theta}^{(i)}=l^2\nabla^2N_{x\theta}^{(i)}+A_{55}^{(i)}\gamma_{x\theta,0}^{(i)}-\tau_i^{(s)}\gamma_{i,X\theta,0}^{(NL)};$$
$$\bar{M}_{xx}^{(i)}=l^2\nabla^2M_{xx}^{(i)}+D_{11}^{(i)}k_x^{(i)}+D_{12}^{(i)}k_\theta^{(i)}+E_{11}^{(i)}\nabla^2w_i-G_{11}\ddot{w}_i;$$
$$\bar{M}_{\theta\theta}^{(i)}=l^2\nabla^2M_{\theta\theta}^{(i)}+D_{11}^{(i)}k_\theta^{(i)}+D_{12}^{(i)}k_x^{(i)}+E_{11}^{(i)}\nabla^2w_i-G_{11}\ddot{w}_i;$$

$$\bar{M}_{x\theta}^{(i)} = l^2\nabla^2 M_{x\theta}^{(i)} + D_{55}^{(i)} k_{x\theta}^{(i)} - E_{22}^{(i)}\left[-\frac{w_{i,x\theta}}{R_i} + \frac{v_{i,x}}{R_i} - \frac{u_{i,\theta}}{2R_i^2}\right];$$

the parameters $A_{11}^{(i)}, A_{12}^{(i)}, A_{55}^{(i)}, E_{11}^{(i)}, G_{11}, D_{11}^{(i)}, D_{12}^{(i)}$ are published in [19].

The i^{th} layer nanotube kinetic energy is the following:

$$T^{(i)} = \frac{I_0}{2}\int_{S_i}(\dot{u}_i^2 + \dot{v}_i^2 + \dot{w}_i^2)dx R_i d\theta, \qquad (11)$$

where ρ and $\rho^{(s)}$ are densities of nanotube and its surfaces; $I_0 = \rho h + 2\rho^{(s)}$.

The considered simply-supported nanotube satisfies the following boundary conditions:

$$v_i|_{x=0} = w_i|_{x=0} = v_i|_{x=L} = w_i|_{x=L} = 0. \qquad (12)$$
$$\bar{N}_{xx}^{(i)}\big|_{x=0} = \bar{M}_{xx}^{(i)}\big|_{x=0} = \bar{N}_{xx}^{(i)}\big|_{x=L} = \bar{M}_{xx}^{(i)}\big|_{x=L} = 0.$$

Three NPDEs of the nanotube oscillations are obtained from the Hamilton principle.

$$\mathbb{\Gamma}_w^{(i)} = I_0\ddot{w}_i + \frac{\bar{N}_{\theta\theta}^{(i)}}{R_i} - \bar{M}_{xx,xx}^{(i)} - \frac{\bar{M}_{\theta\theta,\theta\theta}^{(i)}}{R_i^2} - \frac{2\bar{M}_{x\theta,x\theta}^{(i)}}{R_i} - Q_{x,x}^{(i,s)} - \frac{Q_{y,\theta}^{(i,s)}}{R_i} - \frac{\partial}{\partial x}\left(\bar{N}_{xx}^{(i)} w_{i,x}\right) - \frac{\partial}{\partial\theta}\left[\frac{\bar{N}_{\theta\theta}^{(i)}}{R_i}\left(\frac{w_{i,\theta}}{R_i} - \frac{v_i}{R_i}\right)\right] - \frac{\partial}{\partial x}\left[\bar{N}_{x\theta}^{(i)}\left(\frac{w_{i,\theta}}{R_i} - \frac{v_i}{R_i}\right)\right] - \frac{\partial}{\partial\theta}\left(\frac{\bar{N}_{x\theta}^{(i)}}{R_i} w_{i,x}\right) - p_z^{(i)} = 0;$$

$$\mathbb{\Gamma}_v^{(i)} = I_0\ddot{v}_i - \frac{\bar{N}_{\theta\theta,\theta}^{(i)}}{R_i} - \frac{\bar{M}_{\theta\theta,\theta}^{(i)}}{R_i^2} - \bar{N}_{x\theta,x}^{(i)} - \frac{3\bar{M}_{x\theta,x}^{(i)}}{2R_i} - \frac{\partial}{\partial x}\left[\frac{\bar{N}_{xx}^{(i)} + \bar{N}_{\theta\theta}^{(i)}}{4}\left(v_{i,x} - \frac{u_{i,\theta}}{R_i}\right)\right] - \frac{\bar{N}_{\theta\theta}^{(i)}}{R_i^2}\left(w_{i,\theta} - v_i\right) - \frac{\bar{N}_{x\theta}}{R_i} w_{i,x} - p_\theta^{(i)} = 0; \qquad (13)$$

$$\mathbb{\Gamma}_u^{(i)} = I_0\ddot{u}_i - \bar{N}_{xx,x}^{(i)} - \frac{\bar{N}_{x\theta,\theta}^{(i)}}{R_i} + \frac{\bar{M}_{x\theta,\theta}^{(i)}}{2R_i^2} + \frac{\partial}{\partial\theta}\left[\frac{\bar{N}_{xx}^{(i)} + \bar{N}_{\theta\theta}^{(i)}}{4R_i}\left(v_{i,x} - \frac{u_{i,\theta}}{R_i}\right)\right] - p_x^{(i)} = 0,$$

where the partial derivatives with respect to the index is indicated by the index after comma; $p_x^{(i)}, p_\theta^{(i)}, p_z^{(i)}$ are external forces projections.

The NPDEs (13) are presented with respect to u_i, v_i, w_i in the form:

$$\mathbb{\Gamma}_u^{(i)} = \Lambda\left(I_0\ddot{u}_i - p_x^{(i)}\right) + F_u^{(i)} + \mathcal{L}_u^{(i)} - R_u^{(i)} = 0; \qquad (14)$$
$$\mathbb{\Gamma}_v^{(i)} = \Lambda\left(I_0\ddot{v}_i - p_y^{(i)}\right) + F_v^{(i)} + \mathcal{L}_v^{(i)} + R_v^{(i)} = 0;$$
$$\mathbb{\Gamma}_w^{(i)} = \Lambda\left(I_0\ddot{w}_i - p_z^{(i)}\right) + F_w^{(i)} + \mathcal{L}_w^{(i)} + R_w^{(i)} = 0; i = 1, \dots, N,$$

where $\Lambda(\cdot) = (\cdot) - l^2\nabla^2(\cdot)$; $\mathcal{L}_u^{(i)}, F_u^{(i)}, R_u^{(i)}, \mathcal{L}_v^{(i)}, F_v^{(i)}, R_v^{(i)}, \mathcal{L}_w^{(i)}, F_w^{(i)}, R_w^{(i)}$ are operators.

The van der Waals nonlinear loads act on the every layer of the nanotube

$$p_z^{(i)} = \sum_{j=1}^{N} c_{ij}\left(w_i - w_j\right) + \sum_{j=1}^{N} e_{ij}\left(w_i - w_j\right)^3;$$
$$p_x^{(i)} = p_\theta^{(i)} = 0, \qquad (15)$$

where

$$c_{ij} = -\frac{\varepsilon R_j\pi}{a^4}\left\{\frac{1001\sigma^{12}}{3}E_{ij}^{(13)} - \frac{1120\sigma^6}{9}E_{ij}^{(7)}\right\};$$
$$e_{ij} = -\frac{\varepsilon R_j\pi}{a^4}\left\{\frac{65065\sigma^{12}}{6}E_{ij}^{(15)} - \frac{3920\sigma^6}{3}E_{ij}^{(9)}\right\};$$
$$E_{ij}^{(m)} = \left(R_i + R_j\right)^{-m}\int_0^{\pi/2}\frac{d\theta}{\left(1 - K_{ij}cos^2\theta\right)^{m/2}};$$
$$K_{ij} = \frac{4R_iR_j}{\left(R_j + R_i\right)^2},$$

a is bond length; ε is potential depth; σ is parameter of equilibrium.

III. Nonlinear ordinary differential equation of nanotube motions

The Galerkin technique is used to transform the NPDEs (14) into the system of NODEs. This transformation is discussed in this section. The nanoshell nonlinear vibrations are expanded as:

$$u_i = \sum_{j=1}^{r_i^{(u)}} P_{i,j}^{(u)}(x)\left[q_{i,j}^{(u,c)}(t)\cos(n\theta) + q_{i,j}^{(u,s)}(t)\sin(n\theta)\right] + \sum_{j=1}^{r_i^{(u,0)}} P_{i,j}^{(u,0)}(x)\, q_{i,j}^{(u,0)};$$

$$v_i = \sum_{j=1}^{r_i^{(v)}} P_{i,j}^{(v)}(x)\left[q_{i,j}^{(v,c)}(t)\cos(n\theta) + q_{i,j}^{(v,s)}(t)\sin(n\theta)\right];$$

$$w_i = \sum_{j=1}^{r_i^{(w)}} P_{i,j}^{(w)}(x)\left[q_{i,j}^{(w,c)}(t)\cos(n\theta) + q_{i,j}^{(w,s)}(t)\sin(n\theta)\right] + \sum_{j=1}^{r_i^{(w,0)}} P_{i,j}^{(w,0)}(x)\, q_{i,j}^{(w,0)}, \qquad (16)$$

where

$$P_{i,j}^{(u)}(x) = \sum_{\nu=1}^{g_{ij}^{(u)}} A_{u,\nu}^{(i,j)} cos\left(\frac{\nu\pi x}{L}\right);$$
$$P_{i,j}^{(u,0)}(x) = \sum_{\nu=1}^{g_{ij}^{(u,0)}} A_{u,\nu}^{(0,i,j)} cos\left(\frac{\nu\pi x}{L}\right);$$
$$P_{i,j}^{(v)}(x) = \sum_{\nu=1}^{g_{ij}^{(v)}} A_{v,\nu}^{(i,j)} sin\left(\frac{\nu\pi x}{L}\right);$$
$$P_{i,j}^{(w)}(x) = \sum_{\nu=1}^{g_{ij}^{(w,0)}} A_{w,\nu}^{(0,i,j)} sin\left(\frac{\nu\pi x}{L}\right);$$

n is waves number; $\mathbf{q} = \left(q_1, \dots, q_{N_*}\right) \equiv \left(q_{i,j}^{(u,c)}, \dots, q_{i,j}^{(w,0)}\right)$ is vector of generalized coordinates; $A_{u,\nu}^{(i,j)}, \dots, A_{w,\nu}^{(0,i,j)}$ are coefficients of eigenmodes, which are obtained by the Rayleigh– Ritz method [20].

The Galerkin technique is expressed by the following relations:

$$\iint_{S_i} \mathbb{I}_u^{(i)} P_{i,j}^{(u,0)}(x)\, R_i d\theta dx + \int_0^{2\pi} \left[\bar{N}_{xx}^{(i)} P_{i,j}^{(u,0)}(x)\right]_0^L R_i d\theta = 0;$$

$$\iint_{S_i} \mathbb{I}_u^{(i)} P_{i,j}^{(u)}(x) \begin{Bmatrix}\cos(n\theta)\\ \sin(n\theta)\end{Bmatrix} R_i d\theta dx + \int_0^{2\pi} \left[\bar{N}_{xx}^{(i)} P_{i,j}^{(u)}(x) \begin{Bmatrix}\cos(n\theta)\\ \sin(n\theta)\end{Bmatrix}\right]_0^L R_i d\theta = 0;$$

$$\iint_{S_i} \begin{Bmatrix}\mathbb{I}_v^{(i)} P_{i,j}^{(v)}(x)\cos(n\theta)\\ \mathbb{I}_v^{(i)} P_{i,j}^{(v)}(x)\sin(n\theta)\end{Bmatrix} R_i d\theta dx = 0; \quad (17)$$

$$\iint_{S_i} \begin{Bmatrix}\mathbb{I}_w^{(i)} P_{i,j}^{(w)}(x)\cos(n\theta)\\ \mathbb{I}_w^{(i)} P_{i,j}^{(w)}(x)\sin(n\theta)\\ \mathbb{I}_w^{(i)} P_{i,j}^{(w,0)}(x)\end{Bmatrix} R_i d\theta dx = 0.$$

The equations (17) can be presented as nonlinear dynamical system. This dynamical system has the following matrix form:

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{K}\mathbf{q} + \mathbf{K}^{(\mathbf{B})}\mathbf{q} + \mathcal{P}_{\boldsymbol{F}}^{(\mathbf{2})}(\mathbf{q}) + \mathcal{P}_{\boldsymbol{W}}^{(\mathbf{3})}(\mathbf{q}) + \mathcal{P}_{\boldsymbol{G}}^{(\mathbf{2,3})}(\mathbf{q}) = 0, \quad (18)$$

where $\mathbf{M}$; $\mathbf{K}$ are matrices, which describe the linear part of the system; the term $\mathbf{K}^{(\mathbf{B})}\mathbf{q}$ is linear contribution for nonlinear boundary conditions for $\bar{N}_{xx}^{(i)}$. The nonlinear term $\mathcal{P}_{\boldsymbol{F}}^{(\mathbf{2})}(\mathbf{q})$ is contribution of the nonlinear summands of $\bar{N}_{xx}^{(i)}$ into the NODEs (18).

$$\mathcal{P}_{\boldsymbol{F},i}^{(\mathbf{2})} = \sum_{\nu=1}^{N_*}\sum_{j=1}^{\nu} f_{\nu j}^{(i)} q_\nu q_j .$$

The van der Waals nonlinearity in the equation (18) are described by vector-function $\mathcal{P}_{\boldsymbol{W}}^{(\mathbf{3})}(\mathbf{q})$

$$\mathcal{P}_{\boldsymbol{W},i}^{(\mathbf{3})} = \sum_{\boldsymbol{\nu=1}}^{N_*}\sum_{\boldsymbol{j=1}}^{\boldsymbol{\nu}}\sum_{j_1=1}^{j} w_{\nu j j_1}^{(i)} q_\nu q_j q_{j_1} .$$

The geometrical nonlinearity of nanoshell is described by the vector-function

$$\mathcal{P}_{\boldsymbol{G},i}^{(\mathbf{2,3})} = \sum_{\nu=1}^{N_*}\sum_{j=1}^{\nu} g_{\nu j}^{(i)} q_\nu q_j + \sum_{\boldsymbol{\nu=1}}^{N_*}\sum_{\boldsymbol{j=1}}^{\boldsymbol{\nu}}\sum_{j_1=1}^{j} g_{\nu j j_1}^{(i)} q_\nu q_j q_{j_1} .$$

IV. Nonlinear modes numerical analysis

Here the nonlinear modes are considered in the sense of Rosenberg [21, 22]. In order to calculate numerically these nonlinear modes, the continuation method and shooting approach are applied jointly [23, 24]. The free nonlinear oscillations in the form of nonlinear normal modes are presented in backbone curves. The multipliers are obtained to analyze stability of these periodic motions [25, 26, 27]. The multipliers are eigenvalues of monodromy matrix. This matrix is calculated numerically too.

V. Data of numerical analysis

Nonlinear oscillations of nanoshell with one wall are considered from Si «100» with the surface and bulk parameters:

$$\frac{R_1}{h} = 50;\ E = 210\ GPa;\ \rho = 2331\ kg/m^3;\ \nu = 0.24;$$
$$\lambda^{(s)} = -4.488\ N/m;\ \mu^{(s)} = -2.774\ N/m;$$
$$\tau_1^{(s)} = 0.605\ N/m;\ \rho^{(s)} = 3.17\cdot 10^{-7}\ kg/m^2, \quad (19)$$

where ν is bulk material Poisson ratio; E is Young modulus. The nanoshell geometrical values are:

$$\frac{R_1}{h} = 30; h = 10\ nm;\ L = 4500\ nm.$$

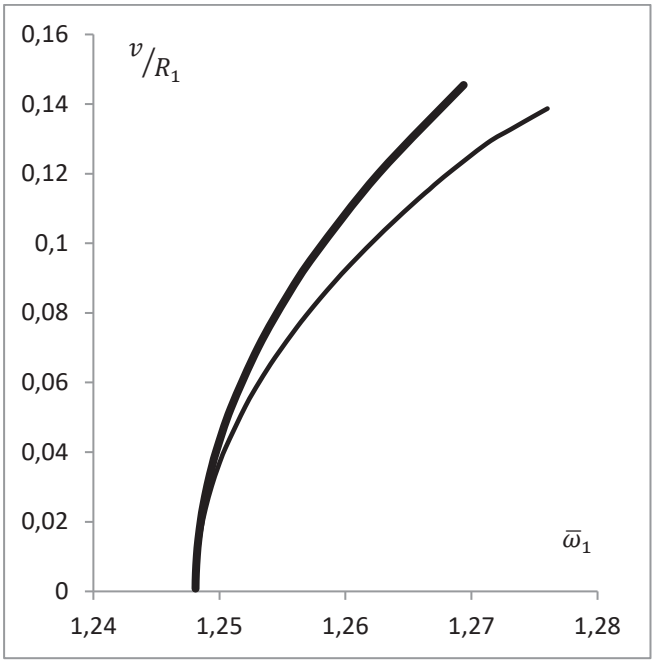

Fig. 2. Nanoshell backbone lines

Two nonlinear systems (18) having eight and fourteen degrees of freedom are obtained. Nonlinear modes of these two systems are calculated by combination of arc length continuation approach and shooting technique. The data of the numerical study are presented on Fig.2, where the dependences of nanotube torsions ν on the frequency $\bar{\omega}_1$ are presented. The thick line shows the nonlinear modes in eight degrees of freedom dynamical system. Thin line shows nonlinear modes in fourteen degrees of freedom dynamical systems. The solutions convergences take place (Fig.2). As follows from the results of numerical simulations, energy exchanges between torsional and radial displacements are observed.

The dependence of nonlinear oscillations on surface effect is considered. The backbone curves taking the surface effect and without one are presented on Fig.3. Thus, the parameters of nonlinear oscillations depend essentially on the surface effect.

Nonlinear oscillations of the nanotube with the parameters (19), the length $L = 7200\ nm$ and wave number $n = 2$ are studied. As follows from the numerical studies, two internal resonances 1:1 are observed in nanotube. The internal resonance is explained by existing of two conjugate modes, which is observes in cylindrical nanoshell. Moreover, two eigenfrequencies is the following: $\bar{\omega}_1^{(n=2)} = 3.1$; $\bar{\omega}_2^{(n=2)} = 3.13$. Thus, these eigenfrequencies meet the condition of the internal resonance 1:1.

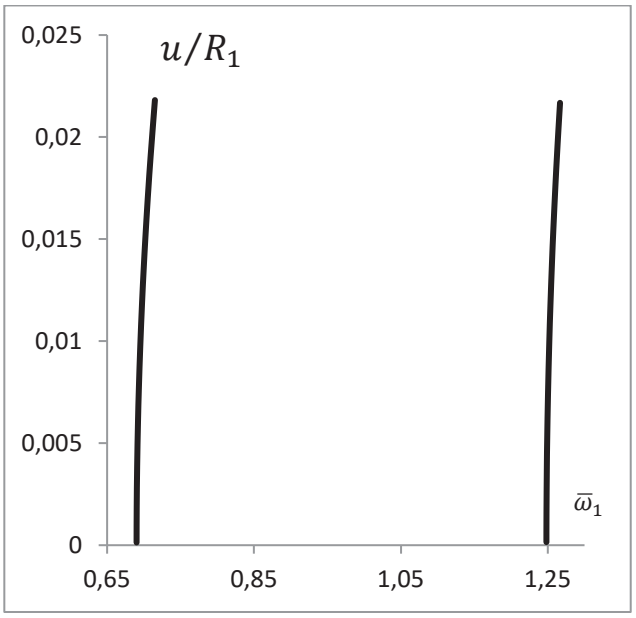

Fig. 3. Nanotube backbone curve with and without surface effect

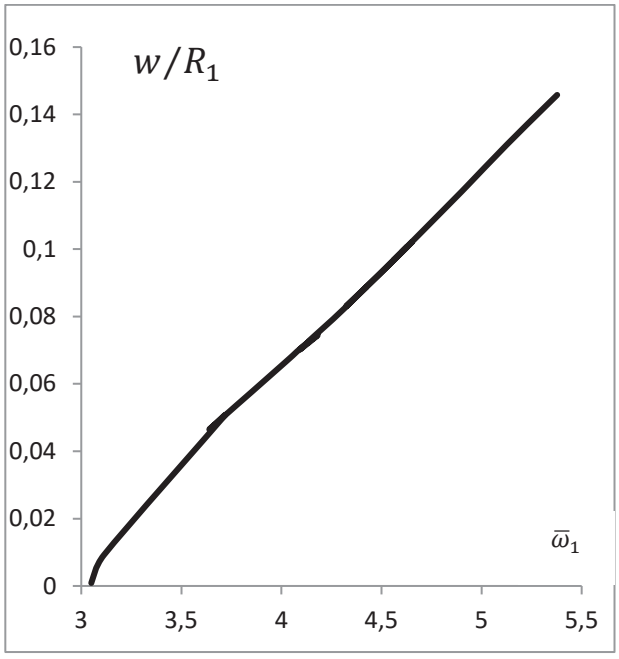

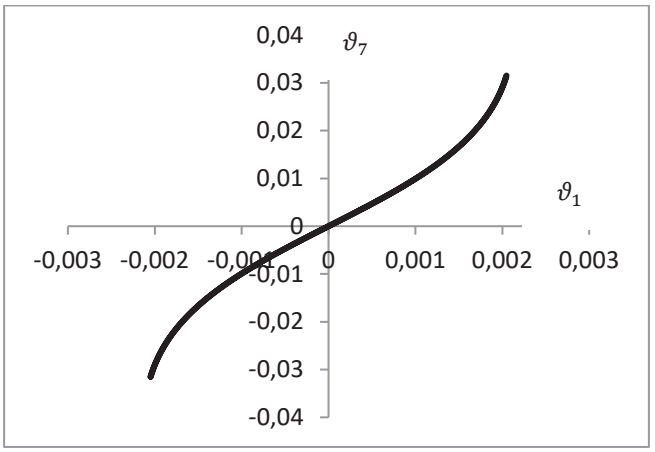

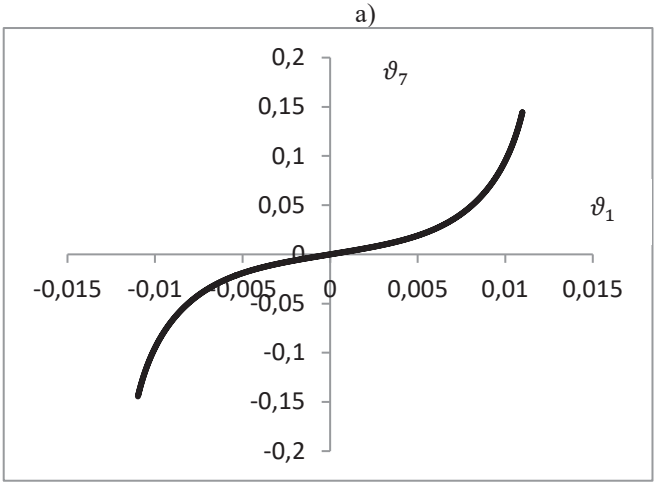

Fig. 4. Backbone curves in the case of two internal resonances

The nanotube travelling waves are considered. Then two conjugate modes (16) are considered. The 14 degrees of freedom nonlinear dynamical system is constructed to study such travelling waves. Fig.4 shows the backbone curve of this dynamical system, which is essentially nonlinear. Thus, the backbone curve is hard. The frequency of nonlinear oscillations belongs to the range $\bar{\omega}_1 \in [3.1; 5.5]$. The amplitudes of radial and torsional motions are closed.

The periodic oscillations, which are shown on Fig.4, are nonlinear modes. These nonlinear modes are essentially curvilinear. The nonlinear modes are analyzed in the configuration subspace $(\vartheta_1, \vartheta_7)$. Two curvilinear nonlinear modes for different values of amplitude of radial displacements a_w are shown on Fig.5.

a)

b)

Fig. 5. Nonlinear modes at radial displacements amplitudes a_w and frequencies $\bar{\omega}_1$: a. $(a_w, \bar{\omega}_1) = (5.13 \cdot 10^{-2}; 3.732)$; b. $(a_w, \bar{\omega}_1) = (1.45 \cdot 10^{-1}; 5.37)$

VI. CONCLUSIONS

Nonlinear mathematical model of nonlinear oscillations of nanotubes is obtained. This model consists of nonlinear ordinary differential equations system. The geometrically nonlinear shell theory with account of nonlocal elasticity, surface effect and nonlinear van der Waalse forces are used to obtain the system of nonlinear partial differential equations. The Galerkin technique is applied to these partial differential equations. As a result, the system of nonlinear ordinary differential equations, which is mathematical model of nanotube, is derived.

As a result of the numerical integration, it is obtained, that the nonlinear oscillations of nanotube are nonlinear normal modes in configuration space. The obtained nonlinear modes are essentially curvilinear.

As follows from the numerical simulations, surface effect affects essentially on nanotube nonlinear oscillations.

***Abstract* - Coal tar is a key by-product of coking processes widely used for producing binders in carbon electrode manufacturing. One of its essential characteristics is the presence of a solid dispersed phase consisting of high-carbon particles, notably the α-fraction (toluene-insoluble substances) and its high-molecular-weight subset, the α_1-fraction (quinoline-insoluble substances). The performance of coal-tar-based binders and impregnation pitches depends significantly on the granulometric composition of this dispersed phase. In this study, we investigated the feasibility of modifying the particle size distribution of the α_1-fraction by initiating hydraulic shock within coal tar using high-voltage electrical discharges in a sealed vessel. Experimental results demonstrate that even a limited number of discharges leads to a measurable reduction in the mass fraction of α- and α_1-fractions due to mechanical disintegration of coarse and agglomerated particles. Scanning microscopy confirms the shift toward finer particle sizes, enhancing the interaction surface between the solid phase and dispersion medium. This transformation improves the infiltration potential of the pitch into porous carbon blanks, potentially increasing impregnation efficiency without compromising coking properties. However, partial reaggregation over time suggests that dispersion should occur at the thermal fractionation stage, where higher viscosity suppresses particle recombination. The findings open new possibilities for tailoring coal tar microstructure to meet advanced requirements in electrode production.**

Keywords - Coal tar, dielectric, granulometric composition, α-fraction, electric discharge, hydraulic shock.

I. Introduction

Coal tar is one of the main products of coke chemical processing, widely used as a binder for carbon electrodes in the aluminum industry, electrometallurgy, and other modern high-tech sectors. These binders possess a number of unique properties that make them virtually irreplaceable materials in a wide range of applications [1], [2]. One of its key properties is the presence of a solid dispersed phase composed of high-carbon particles — substances insoluble in toluene (known as the α-fraction or TI). Within this fraction, a high-molecular-weight component with the highest degree of pyrolysis and properties closest to carbon materials is further distinguished: the quinoline-insoluble substances (α_1-fraction, QI or so named “carbon blacks”). During the processing (rectification) of coal tar pitch, the aforementioned components almost entirely transfer into the non-distillable residue, which serves as the raw material for the production of binder materials.

Another common indicator of the composition of the solid dispersed phase of coal tar is the mass fraction of the α2-fraction (otherwise - β-rezines). However, this indicator is of purely auxiliary importance, its value is determined as the arithmetic difference between the values of QT and QI, and therefore does not provide additional information from the point of view of the purpose of the studies presented in this article.

The homogeneity, and therefore the binding and plastic properties of the dispersed system, improves with greater interaction between the solid carbonaceous dispersed phase and the dispersion medium. This interaction depends, among other factors (e.g., surface condition, particle shape, wettability), on the specific surface area of the dispersed phase. A higher content of finely dispersed α1-fraction in the pitch increases this surface area and thus enhances its interaction with the dispersion medium. Moreover, this interaction can be strengthened by the “activation” (radicalization) of particle surface fragments through mechanical disruption.

In carbon electrode manufacturing—especially for graphitized electrodes—an additional stage is commonly applied: impregnation of the baked body with a special binder known as impregnation electrode pitch, also obtained as the non-volatile residue from coal tar rectification. In this context, modifying the granulometric composition of the dispersed phase toward smaller fractions becomes particularly important. Various sources estimate the average pore diameter of electrode blanks to fall within the range of 1–45 μm. It has been shown that decreasing the content of particles within this size range in the pitch can increase the degree of impregnation by 2–5% [3].

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

Our previous research [4] confirmed that the particle size of a significant (if not dominant) portion of coal tar's solid phase corresponds to the typical pore sizes of electrode blanks. Thus, transforming part of the α1-fraction into the 0–1 μm range can improve the penetration ability of the impregnation pitch without impairing its coking performance.

Our previous studies [4], [5] also demonstrated a high tendency of α_1-fraction particles to form aggregates. Microscopic analysis makes it possible to distinguish between primary aggregates, which are formed in the free-space zone under the roof of the coke oven and are resistant to dissolution of the tar in organic solvents, and secondary aggregates, which are formed during the condensation of coal tar from the vapor phase, as well as during storage, transportation, and other technological stages involving heating under conditions that reduce tar viscosity (see Fig. 1 and 2).The reduction in tar viscosity ensures the mobility of microscopic dispersed particles, which, in combination with specific surface activity characteristics, promotes their aggregation. Under conditions where heating leads to an increase in the viscosity of the liquid phase (e.g., during distillation or rectification), aggregation is expected to be hindered.

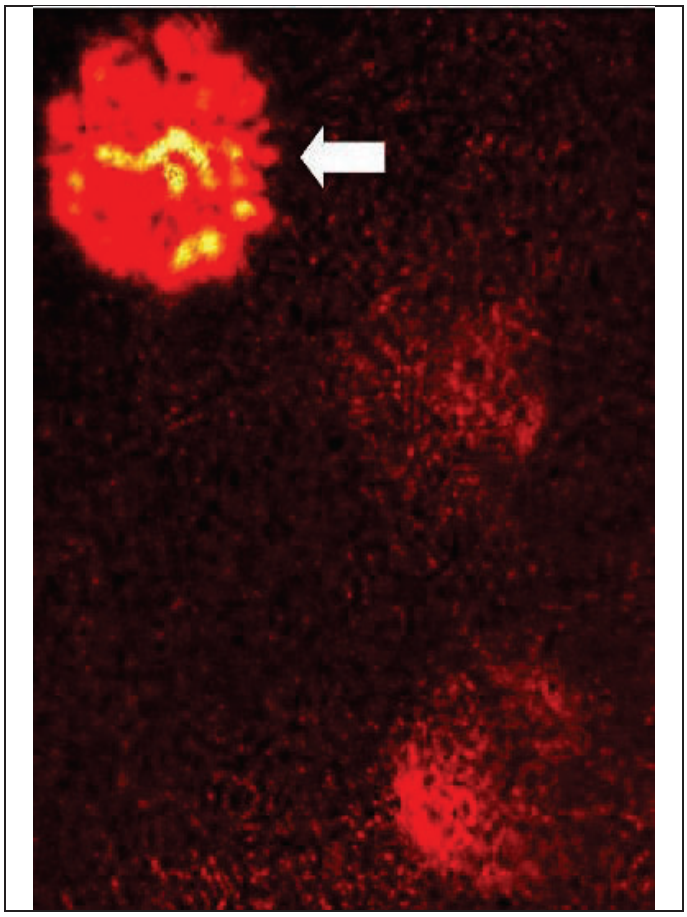

Fig. 2. Aggregation of α_1-fraction particles during viscosity reduction of coal tar by dissolution in quinoline, observed under laser beam illumination at an angle to the sample plane (microscope magnification ×800)

II. Materials and Methods

We evaluated the fundamental feasibility of dispersing α-fraction particles through hydraulic shock initiated in coal tar confined within a sealed vessel. A hydraulic shock is a sudden pressure increase that propagates as an elastic wave in all directions from the initiation center. Upon reaching the vessel wall, part of the pressure is absorbed, and the drop in pressure is reflected back toward the initiation point.

In the hydraulic shock zone, suspended α_1-fraction particles experience an abrupt increase in surface pressure, leading to fragmentation. Aggregates and large irregular particles are the most susceptible to such destruction.

An electric discharge was used as the initiator of the hydraulic shock. Since coal tar is a dielectric, discharge theoretically can occur with dielectric breakdown — loss of dielectric properties under an electric field exceeding a certain strength.

The dielectric properties of coal tar remain insufficiently studied, and the available data reported in various sources vary significantly. This inconsistency is due to the complexity of its composition and substantial differences in the properties of coal tars produced by different manufacturers.

Generally, coal tar is a complex physicochemical system, with a number of components present in an emulsified or dispersed state. The major part of this material consists of aromatic hydrocarbons. The presence of solid

carbonaceous particles (commonly referred to as “carbon blacks”) and water globules with varying salt content significantly affects the dielectric permittivity threshold of coal tar.

As for the dispersion matrix of coal tar itself, it exhibits high electrical resistance. For example, a protective mastic used for pipeline insulation, based on anhydrous coal tar, demonstrates the following parameters (ShaliEnamel. “Coal Tar Enamel for Pipe Coating,” Url: https://stpltd.com/wp-content/upload/TDS/ShaliEnamel.pdf.):

- Electrical resistance, 10000 volts/mm – No breakdown;
- Dielectric strength, kV/mm, Min – 10;
- Volume resistivity, ohm·cm, Min – 10^{13}.

Therefore, one of the objectives of this study was to refine certain dielectric characteristics of raw coal tar, particularly the threshold of its dielectric permittivity.

It is known, that in liquids containing water impurities, the breakdown is preceded by the formation of a conductive channel between electrodes. Water droplets polarize and elongate under the electric field, forming ellipsoids that merge and, under sufficient field strength, create a highly conductive channel. This results in rapid heat release, liquid boiling, and a gaseous discharge along the vapor channel. Similar effects are observed in dielectrics with solid conductive inclusions (e.g., carbon particles) [6].

In our case, the coal tar contained both conductive solid inclusions and water (3.7%). The explosive boiling of liquid in the discharge zone inside the sealed vessel served as the initiator of the hydraulic shock.

Under such conditions of hydraulic shock initiation, an additional source of physical impact on the solid-dispersed particles is the cavitation effect, which arises due to the boiling not only of water but also of the light fractions of coal tar under hydrodynamic cavitation. It is well known that cavitation effects are used, for example, in wet coal grinding to produce fine coal suspensions in liquid dispersive media [7]. To some extent, this can be regarded as a simplified analogue of the effect we aimed to achieve in our study.

The characteristics of the initial coal tar are presented in Table 1.

TABLE I. CHARACTERIZATION OF THE INITIAL COAL TAR

Parameter	**Coal Tar Sample 3**
Density (dry mass), kg/m³	1197
Moisture content, %	3.7
Mass fraction of α_1-fraction, %	5.8
Mass fraction of α-fraction, %	11.1
Ash content, %	0.22
Distillation characteristics – mass fraction distilled at temperature range, °C, %: – up to 180 – 180–200 – 200–230 – 230–300 – 300–360 – above 360 – losses	 1.8 0.5 16.1 8.7 12.4 60.2 0.3

The electric circuit of the laboratory setup included a DC power supply, a capacitor, and an insulated discharge cell with two oppositely oriented electrodes. After static breakdown was achieved, the electrical discharge parameters necessary to initiate hydraulic shock in the tar were determined: voltage – 50 kV, capacitor capacity – 100 pF, discharge duration – 100 μs.

The efficiency of dispersion was assessed by the reduction in the mass fractions of quinoline-insoluble (α_1-fraction) and toluene-insoluble (α-fraction) substances, using the standard hot filtration method. It is worth noting that according to TU U 17.1-2510012269-001:2015 “Laboratory filter paper”, the density of filter papers used in this method is not specified by pore size (which is nearly impossible to define for paper materials) but by the duration of distilled water filtration through a funnel-shaped folded filter.

Therefore, paper filters are unsuitable for precise granulometric analysis of the solid dispersed phase using screening techniques. Nevertheless, as shown later, the hot filtration method provides insight into the behavior of solid dispersed particles under the studied conditions.

III. RESULT AND DISCUSSION

Coal tar subjected to electric discharge was analyzed for toluene-insoluble (α-fraction) and quinoline-insoluble (α_1-fraction) content. The results are presented in Table 2.

The experimental data show that the α-fraction content in tar decreases after exposure to hydraulic shock. The difference between the untreated tar and the sample subjected to 50 discharges is significant—over 2% absolute—which is approximately four times higher than the margin of analytical error.

A similar trend is observed for the α_1-fraction. and the reduction in both fractions suggests that the decrease in toluene-insoluble substances is predominantly due to a reduction in the quinoline-insoluble component.

TABLE II. EFFECT OF HYDRAULIC SHOCKS ON COAL TAR PROPERTIES

Indicator	**Number of Discharges**			
	0	**1**	**5**	**50**
Mass fraction of α-fraction, %	11.1	10.4	9.5	8.9
Reduction in α-fraction per discharge. % abs.	–	0.70	0.32	0.04
Mass fraction of α_1-fraction. %	5.8	4.9	4.0	3.8
Reduction in α_1-fraction per discharge. % abs.	–	0.80	0.36	0.08

Since significant chemical changes of the solid dispersed phase are unlikely under the given experimental conditions, we assume that the hydraulic shock induced by electric discharge causes the mechanical destruction of quinoline-insoluble particles—likely aggregates in particular. As a result of this fragmentation, dispersed particles of reduced size are able to pass through the pores of the filter during analysis, thereby creating the appearance of a reduced α- and α_1-fraction content. This observation is consistent with our earlier research, which confirmed that the proposed method provides a reliable estimation of the average particle size within the α_1-fraction.

To illustrate this, Table 3 presents the results of determining the mass fraction of quinoline-insoluble substances, obtained using the standardized hot filtration method, for tars sampled at various stages of pyrolysis (sample B corresponds to the tar used in the present study). According to the standard procedure, two layers of "white ribbon" filter paper are typically employed. However, in order to better understand the filtering process, we conducted additional measurements under otherwise identical conditions using one and three filter layers. As shown in the table, the measured yield of the target fraction consistently increases as the number of filter layers is raised. This trend strongly suggests that the standard filter configuration permits at least some α_1-fraction particles to pass through, meaning the obtained values may underestimate the true content.

Thus, there is no doubt that with an increase in the number of filter layers, the number of small-class particles captured on the filter also increases. This finding further supports the assumption that the apparent reduction in fraction content observed after electrical discharge treatment is not due to chemical decomposition but rather due to changes in particle size distribution.

TABLE III. EFFECT OF FILTER MATERIAL DENSITY ON THE DETERMINATION OF THE A1-FRACTION MASS CONTENT

Sample	Number of "white ribbon" filter paper layers		
	1	2 (standard)	3
A	4.3	6.1	6.2
B	4.4	5.8	5.9
C	3.9	4.7	5.4

However, to verify the conclusion that the decrease in the mass fraction of the fractions studied is caused by a decrease in the size of their particles, we investigated the granulometric composition of the α_1-fraction in both untreated and 50-discharge-treated tar using a method based on scanning microscopy [8]. The results are presented in Figure 3. which also shows the composition of the solid phase after 38 hours of aging at 80°C.

The data clearly confirm that hydraulic shock treatment results in a pronounced shift in the granulometric distribution of the solid phase toward finer particles. Consequently, the observed decrease in high-molecular-weight components in Table 2 can be explained by the transformation of the material into ultrafine fractions that are capable of passing through the filter during analysis.

Conversely, the long-term exposure of tar to typical storage and pumping temperatures leads to partial restoration of the original particle size distribution. This finding provides further support for our earlier assumption that dispersion of the solid phase is most effective when performed during a technological stage that simultaneously increases the viscosity of the dispersion medium—namely, during thermal fractionation—since under these conditions re-aggregation of particles is significantly hindered [5].

Taken together, these results demonstrate that the reduction in α- and α_1-fraction content observed after electrical discharge treatment is primarily a mechanical effect associated with particle size reduction rather than a chemical transformation. The choice of filtration conditions plays a crucial role in correctly interpreting the data, as filters with insufficient retention capacity may allow ultrafine fractions to pass through. Furthermore, the tendency of the solid phase to partially re-aggregate under typical storage conditions highlights the importance of integrating dispersion processes into stages of technological treatment where viscosity is high and re-aggregation is minimized. This ensures more stable and reliable modification of the solid dispersed phase, with potential implications for improving tar processing efficiency and product quality.

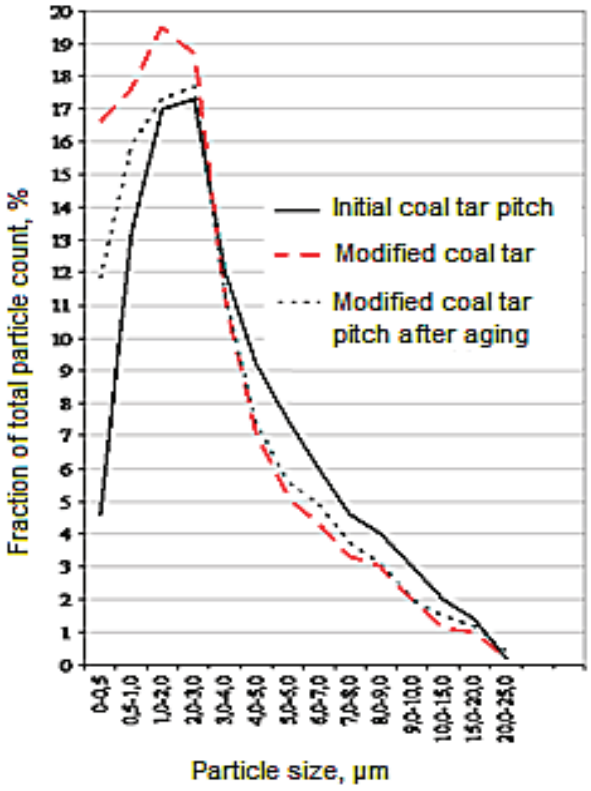

Fig. 3. Granulometric composition of the solid-dispersed phase of untreated and processed coal tar

IV. CONCLUSIONS

Hydraulic shock initiated by electric discharge is an effective method for dispersing the solid dispersed phase of coal tar—particularly the quinoline-insoluble (α_1) fraction. This is evidenced by the reduction in their mass content (via hot filtration) and by the granulometric redistribution toward finer particles.

A reduction in coal tar viscosity enhances the mobility of microscopic dispersed particles, facilitating their aggregation due to surface activity. Conversely, processes that increase liquid phase viscosity (e.g., distillation or rectification) impede aggregation.

Under hydraulic shock initiation, cavitation—resulting from boiling of both water and light tar fractions—provides additional physical impact on solid particles.

The reduction in α- and α_1-fraction content is not due to chemical degradation, but rather to mechanical disintegration, which causes particles to pass through filter pores during analysis

Dispersion increases the specific surface area of the solid phase, improving its interaction with the dispersion medium. This can significantly enhance the properties of binders and impregnation pitches derived from coal tar.

Ultrafine α_1-fraction particles (0–1 μm) penetrate more easily into the pores of graphitized electrode blanks, increasing impregnation without compromising coking capacity.

However, the dispersion effect is temporary: prolonged storage leads to partial re-aggregation. Therefore, this treatment is best applied during thermal fractionation, where aggregation is limited due to increased viscosity of the non-volatile residue.

The presented studies were undertaken with the aim of proving the fundamental possibility of adjusting the granulometric composition of the solid dispersed phase of coal tar.

***Abstract*— To develop a numerical two-dimensional field mathematical model of a contactless high-speed permanent magnet motor to estimate its parameters, characteristics and determine the magnitude of losses in the magnetic core under different control methods. Methods. The finite element method was used to calculate the electromagnetic field distribution in the computational domain of the motor under study. To develop two-dimensional and three-dimensional drawings of the design area, methods and tools of computer-aided design were used. Numerical methods for calculating losses in the magnetic core developed by Giovanni Bertotti were used to calculate losses in the magnetic core. The Fourier series expansion method and spectral analysis methods were used to model various motor control methods. Results. A two-dimensional numerical circular-field mathematical model of a contactless high-speed motor with permanent magnets has been developed. The model was developed to estimate the distribution of the electromagnetic field and eddy currents in the structural and active elements of the motor in question in order to determine the magnitude of losses under different power supply methods. The paper investigates the dependence of losses in individual structural elements of the motor under study when powered by a sinusoidal voltage source and when powered by a PWM inverter. Replacing permanent magnets with rectangular magnets reduces the cost of motor manufacturing. The use of rectangular permanent magnets reduces losses in the computational domain, the magnitude of electromagnetic torque fluctuations, but reduces the magnitude of traction. Scientific novelty. Using the developed numerical circular-field mathematical model, it is proved that losses in the magnetic core of a high-speed motor and its structural elements significantly depend on the control method and configuration of the magnetic system and the motor as a whole. The study allows solving urgent scientific and practical problems related to the optimization of the structure depending on next criteria: reduction of heating or losses, reduction of vibration and noise, etc.**

Keywords*— high-speed motor, mathematical simulation, permanent magnets, losses in the magnetic core, electromagnetic torque.

I. Introduction

The overall dimensions of electromechanical energy converters (EMCs) significantly depend on the rotor speed or frequency of the supply voltage; it is known that the higher the rotational speed, the smaller the overall dimensions.

High-speed permanent magnet motors are experiencing a trend towards higher power density and smaller dimensions. Increasing the rated speed of rotation reduces the size and weight of electric machines, making them more efficient for applications where weight, compactness and performance are critical.

The development of new high coercive permanent magnets and the use of CNC tools for EMF production leads to the emergence of new types of electric motors that meet the growing requirements for energy efficiency, reliability and compactness [1, 2]. At the same time, increasing the speed of motors requires an increase in the accuracy of design and manufacturing, causes an increase in losses and heating, and raises certain issues related to dynamic stability [3, 4]. To solve these problems, it is necessary to use modern approaches, methods and tools of mathematical modelling that provide accurate analysis and allow optimization of engine parameters [5]. Modern application packages for numerical mathematical modelling allow for calculations when electromagnetic, thermal and mechanical processes occurring in the system interact and their impact on the parameters and characteristics of an electric motor or EMF.

High-speed motors are those that operate at speeds exceeding several tens of thousands of revolutions per minute [6], which opens up wide opportunities for their application. For example, such motors are used in compressors, medical equipment, high-speed spindles for machining machines, and even in modern electric vehicles. However, at high speeds, it is important to take into account factors that affect the stability of the motor, such as heating, vibrations, electromagnetic losses, and mechanical deformations [7, 8].

Brushless high-speed permanent magnet motors (BHSPMM) are increasingly used in various industries, transport, aviation, power generation, power tools, household appliances, etc. [9]. They have certain key advantages that are a prerequisite for their proliferation: high specific power, low weight, relatively small overall dimensions, no mechanical contacts and minimal maintenance due to reduced wear. These motors are also used in a variety of specific applications that require minimal size and weight, high speed, accuracy and reliability [10].

When developing, designing and optimizing BWDMs, it is necessary to take into account the multiphysical processes occurring in the core of this type of EMF: temperature, losses, magnetic induction values in individual parts of the magnetic

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

core, etc., which determines reliability, efficiency and maintainability [11].

In addition, the accurate determination of magnetic core losses is important for the analysis of efficiency, losses, temperature.

II. Materials and Research Findings

A three-dimensional geometric model of the prototype of the studied contactless high-speed motor with permanent magnets is shown in Fig. 1.

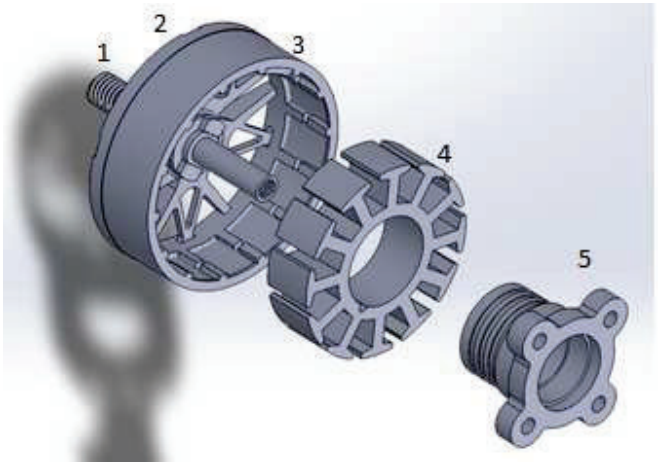

Figure 1. Design of the studied BHSPMM [10]

In Fig. 1 is show: 1 - rotor shaft; 2 - rotor end cover; 3 - rotor bushing with permanent magnets; 4 - stator magnetic core; 5 - stator bushing.

The shaft is made of magnetic steel and has a through bore. The rotor end cover is mounted at the output end of the shaft and is configured to improve motor cooling at high speeds. The cover is made of a single piece of lightweight non-magnetic but electrically conductive material. The rotor bushing is made of a solid (not ring-shaped) magnetically conductive material, which has protrusions in the internal bore in the radial and axial directions for fixing the PM.

The permanent magnets are mounted between the protrusions on the inner surface of the rotor hub and are magnetized radially. The PMs have a complex radial shape that follows the arc of the internal bore of the rotor hub on one side and allows for a uniform air gap between the stator and rotor of the motor.

The motor stator (stator magnetic core) is made of charged plates made of electrical steel. The stator bushing is made of a lightweight non-magnetic alloy as a single piece. Two bearings (not shown in Fig. 1) are installed in the inner part of the bushing. The stator winding is placed in the grooves of the stator magnetic core and connected in a triangle pattern [10].

The main design parameters of the BHSPMM prototype used to develop the mathematical model are given in Table 1 [8], [9]. The permanent magnets are made of sectoral magnets with homogeneous magnetization in the radial direction from neodymium-iron-boron alloy N52H with a residual magnetic induction of 1.36 T at 20 °C.

For the calculation, it is assumed that the magnetic core of the stator is made of cold-rolled isotropic electrical steel grade 2411. It is assumed that the rotor bushing is made of a composite magnetically soft material based on Somaloy. The high-speed rotor shaft is made of structural steel grade 45.

Based on the data in Table 1, a geometric model is developed and then imported into the COMSOL Multiphysics numerical modelling environment.

The problem is solved by the finite element method. The electromagnetic field and characteristics of the motor under study are analyzed in a two-dimensional approximation, taking into account the following simplifications and assumptions:

1. The axial length of the BHSPM is taken into account empirically, i.e., longitudinal end effects are not taken into account;
2. The properties of electrical steel of the magnetic core are determined by the main magnetization curve, magnetic hysteresis is not taken into account;
3. Since it is difficult to accurately account for the full magnetization and demagnetization curve of permanent magnets, their characteristics are determined only by the residual magnetic induction and coercive force;
4. The magnetic induction vector is considered to be tangent to any point within the computational domain.

The distribution of the electromagnetic field in the computational domain of the study motor is described by equations with respect to the vector magnetic potential and supplemented by boundary conditions with respect to known magnetic field sources:

$$\nabla^2 A = \mu \nabla \times M; \tag{1}$$

$$n \times (A_1 - A_2) = 0; \tag{2}$$

$$n \times \left([\mu_0^{-1} \nabla \times A - M] - [\mu_0^{-1} \nabla \times A - M] \right); \tag{3}$$

$$n \times A_{in} = 0, \tag{4}$$

where: $\boldsymbol{A}$ is the vector magnetic potential, Vb/m; $\boldsymbol{M}$ is the magnetization vector, A/m; A_{in} is the vector magnetic potential at the outer boundary of the computational domain, Vb/m; $\boldsymbol{A_1}$, $\boldsymbol{A_2}$ are the vector magnetic potentials at the boundary of adjacent domains 1 and 2, Vb/m; n is the normal vector.

The electromagnetic torque of a high-speed motor is calculated using the Maxwell's magnetic tension tensor, which has proven to be a reliable method for determining this kind of force [11]. The magnitude of the force acting on the outer rotor of the motor under study is determined by the following expression:

$$f = \mu((nH)H - 0{,}5nH^2, \tag{5}$$

where $\boldsymbol{H}$ is the magnetic field intensity vector, A/m:

$$H = \mu^{-1} \nabla \times A - M. \tag{6}$$

The total electromagnetic torque is the result of integrating the electromagnetic forces acting between the external rotor and stator of the motor and is calculated as follows:

$$T_{em} = \int_{S_g}^{-} (r - r_0) \times f dS, \tag{7}$$

where: S_g is the integration area, f is the distribution of electromagnetic force on the inner surface of the rotor of a high-speed motor under study.

Losses in the stator magnetic core were obtained using the modified Bertotti equation [12] as a result of calculating the magnetic field inside the motor computational domain for each harmonic. The value of losses in the magnetic core is calculated according to the following expression:

$$Q_c = k_h \cdot (n \cdot f)(|\boldsymbol{B}|)^{\beta} + k_c \cdot \sigma \cdot n \cdot f^2 \cdot |\boldsymbol{B}|^2 + 8 \cdot \sqrt{\sigma \cdot G \cdot S \cdot V_0} \cdot (n \cdot f)^{1,5} \cdot (|\boldsymbol{B}|)^{1,5}, \quad (8)$$

Where: $Q_{(c)}$ is the total losses in the magnetic core; σ is the electrical conductivity of the blended magnetic core; G is a constant in the equation, which is taken equal to 0.1356 ; S is the area of the computational domain for which the losses are determined; V_0 is the excess loss coefficient; $k_{(c)}$ is the coefficient of eddy current losses determined by the thickness of the electrical steel sheet; n is the ordinal number of the harmonic; β is the exponential coefficient for magnetic induction; f is the frequency of the fundamental harmonic; kh is the hysteresis loss coefficient.

The eddy current loss factor k_C describes the eddy current losses in the magnetic core and is determined by the thickness of a single sheet of electrical steel:

$$k_c = \frac{\pi^2 \cdot d^2}{6}, \quad (9)$$

where: d is the thickness of a single sheet of electrical steel of the charged magnetic core of the stator of the motor under study.

Equation (8) has three components responsible for: the first component corresponds to the hysteresis losses; the second component characterizes the eddy current losses; the third component describes the excess losses arising from the rotor rotation of the motor under study, according to the Bertotti method.

The hysteresis loss factor kh, eddy current loss factor k_C and excess eddy current loss factor are a function of the current frequency.

Losses in other electrically conductive elements of the design domain of the motor under study (PM, rotor sleeve, shaft, stator winding [13]) were calculated using the following expression:

$$Q_j = {}^1\!/_T \int_{T_1-T}^{T_1} J \cdot E dt, \quad (10)$$

where: T, T_1 - the period of time for which the losses are calculated; J - the current density in the calculation area; E - the electric field strength.

Table 1 – Main design parameters of the prototype BHSPMM

TABLE I. MAIN DESIGN PARAMETERS OF THE PROTOTYPE BHSPM

№	Parameter	Value
1	Number of rotor pole pairs	7
2	Rotor outer diameter, mm	36,0
3	Axial rotor length, mm	9,5
4	Axial length of the stator magnetic core, mm	8,0
5	Residual magnetic induction of the PM, T	1.36 (N52H)
6	Outer diameter of the stator magnetic core, mm	30,0
7	Stator magnetic circuit material	Steel 2411
8	Rotor hub material	Samoloy
9	Rotor inner diameter, mm	33,2
10	Electrical conductivity of permanent magnets, MSm/m	0,56
11	Electrical conductivity of Somaloy, MSm/m	0,14
12	Height of permanent magnets, bmag, mm	1,5
13	Inner/outer diameter of permanent magnets, mm	30,4/33,4
14	Maximum rotor speed, rpm	29100
15	Air gap size, mm	0,2
16	Diameter of the winding wire, mm	0,25
17	Maximum power, W	1300
18	Rated supply voltage, V	24,0

Also, losses in the stator magnetic core were obtained using the modified Bertotti equation as a result of calculating the magnetic field inside the motor computational domain for each harmonic.

III. LOSSES AT DIFFERENT POWER SUPPLY TYPES

The estimation of losses in the computational domain of the motor under study is determined by expressions (1), (2). The division of losses into losses in the magnetic core, PM, rotor sleeve and armature winding is performed by integrating the volumetric losses in each area separately. Obviously, in this case, the magnitude of losses in structural elements is determined by the rotation speed (supply voltage frequency) and the magnitude of magnetic induction in individual motor sections.

The shape of the motor supply voltage curve and the spectral decomposition when powered by a PWM inverter show on Fig. 2.

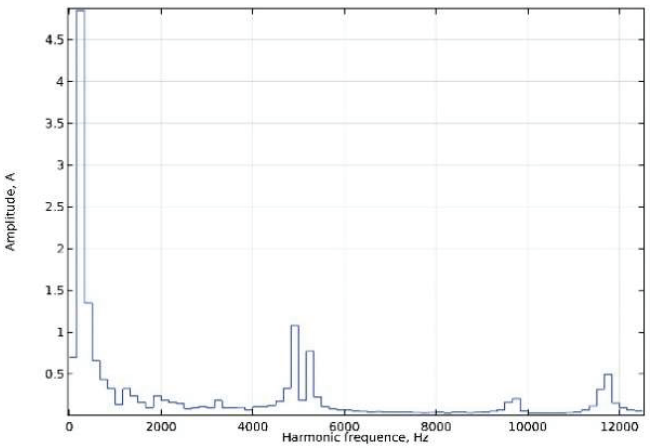

Figure 2. *The voltage supply curve shape and the spectral decomposition when powered by a PWM inverter*

In the spectrum of the supply voltage curve, the main harmonic occupies the main weight, and there are also clearly expressed harmonics of the order of 24, 32, 56, 58, etc.

Obviously, these are high-frequency harmonics and they lead to an increase in losses.

TABLE II. RESULTS OF CALCULATION OF LOSSES AND ELECTROMAGNETIC TORQUE AT DIFFERENT POWER SUPPLY METHODS

n, (rpm)	T_{em} (Н·м)		sin power supply	PWM
	sin	PWM	Losses, (W)	Losses, (W)
3000	0,505	0,491	21,67	35,14
6000	0,735	0,722	28,45	46,65
9350	0,965	0,951	38,41	65,68
12500	1,270	1,259	56,4	102,27
16500	1,487	1,473	74,5	138,95
19000	1,704	1,691	107,17	182,78

Dependence of motor losses on rotational speed show on Fig. 3.

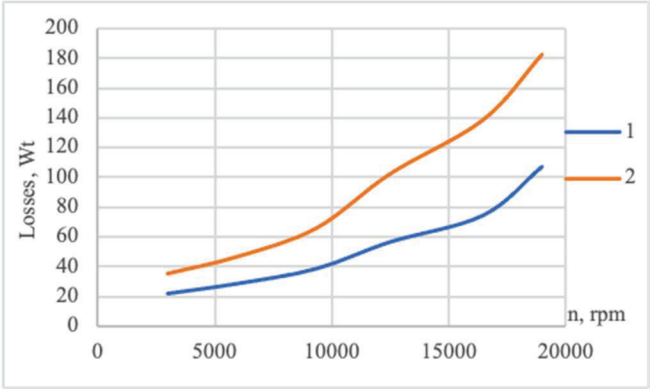

Figure 3. *Dependence of motor losses on rotational speed*

The curves in Fig. 3 represent two types of power supply for the motor under study:

1 — power supply from a sinusoidal voltage source;

2 — power supply of the motor from a PWM inverter.

Obviously, as the rotational speed increases, the losses increase. This is due to an increase in the magnetisation frequency and, accordingly, an increase in hysteresis and eddy current losses. In other electrically conductive structural elements (rotor sleeve, stator winding), losses increase due to the amplification of the current displacement effect, which manifests itself with an increase in rotational speed and supply voltage frequency.

When the motor is powered by a PWM inverter, the losses increase by approximately 53–62% depending on the rotation speed. This is due to an increase in losses from higher harmonics when the motor is powered by a PWM converter. In addition, losses in the design domain increase nonlinearly: when the rotation speed increases by a factor of 2, the losses increase by ≈30%; when the rotation speed increases by a factor of 3, the losses increase by ≈77%; when the speed increases by a factor of 4, the losses increase by ≈260%.

At maximum rotational speeds of 20,000 rpm, the losses increase by ≈5.4 times compared to the initial rotational speed of 3,000 rpm. This is due not only to the increase in the magnetisation frequency, but also to the increase in active resistance due to the enhanced effect of current displacement in the conductive medium.

IV. LOSSES AND TORQUE WITH MODIFIED PM

The radial-shaped PMs are used in the prototype of the BHSPMM under study. On the one hand, this ensures the uniformity of the air gap and allows filling the useful volume with permanent magnets to the maximum extent possible, which allows obtaining the maximum performance characteristics: power and torque in a given volume [9]. Distribution of the electromagnetic field at different shapes of the PM shows on Fig. 4.

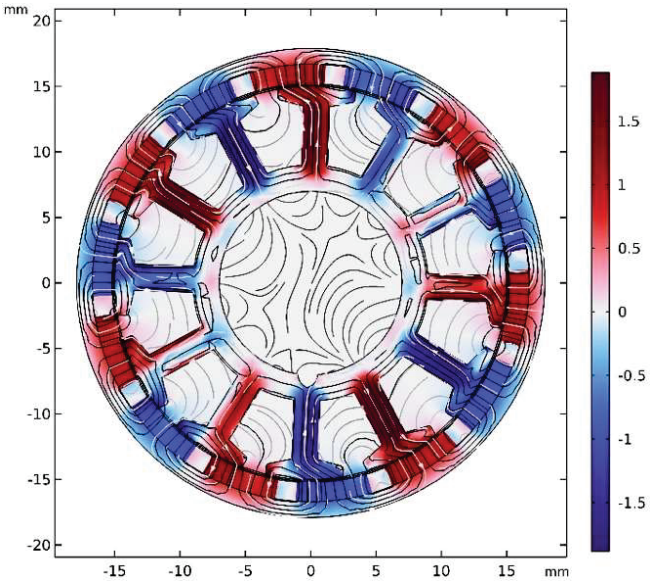

Figure 4. Distribution of the electromagnetic field at different shapes of the PM

However, this form of motor also has disadvantages: manufacturing a motor with this configuration is much more expensive and requires special expensive equipment, and unification is virtually impossible, which leads to an increase in the cost of the manufactured motor. It is possible to reduce the cost of manufacturing a serial sample of this type of motor by using rectangular motor shapes.

The dimensions of the rectangular PMs are selected so that the minimum air gap remains unchanged and is ≈0.2 mm. Obviously, the use of rectangular shaped PMs leads to a decrease in the volume occupied by PMs by ≈23%. This leads to a decrease in the electromagnetic torque, power, and magnetic induction in certain parts of the magnetic system. On the other hand, the magnitude of losses is reduced, both by reducing the magnitude of induction and by reducing the influence of longitudinal end effects. This will lead to reduced motor heating, increased efficiency and operational reliability.

To estimate the losses and the magnitude of the traction force (electromagnetic torque), a series of calculations were carried out for a motor with a rectangular PM shape. The results of calculating the losses in the computational domain when powered by a sinusoidal voltage source and when powered by a PWM inverter are shown in Table III.

TABLE III. RESULTS OF THE CALCULATION OF BHSPMM LOSSES UNDER DIFFERENT FORMS OF PM

n, (rpm)	Prototype		Rectangular PMs	
	sin power supply Losses, (W)	PWM losses, (W)	sin power supply Losses, (W)	PWM losses, (W)
3000	21,67	35,14	17,31	28,07
6000	28,45	46,65	21,86	35,84
9350	38,41	65,68	27,42	46,88
12500	56,4	102,27	41,75	75,7
16500	74,5	138,95	49,17	92,38
19000	107,17	182,78	68,6	116,99

Dependence of losses on the shape of the PM are show on Fig. 5.

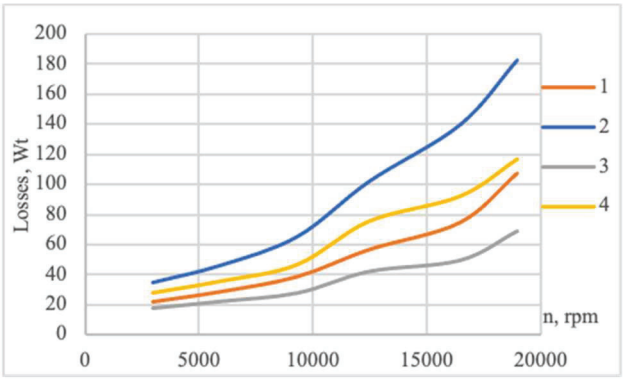

Figure 5. Dependence of losses on the shape of the PM

Fig. 5 shows: 1 – prototype motor losses at sinusoidal power supply voltage; 2 – prototype motor losses when powered by a PWM inverter; 3 – motor losses at sinusoidal power supply voltage and rectangular PM shape; 4 – motor losses when powered by a PWM inverter and rectangular PM shape.

In general, depending on the rotational speed, motor losses when using a rectangular PM shape are reduced by 20–36%.

When changing the configuration of the PM, the value of the electromagnetic torque changes. The dependence of the electromagnetic torque at different shapes of the PM on the rotational speed is shown in Figure 5.

CONCLUSIONS

The study of high-speed permanent magnet motors for their use in various devices and systems is of great scientific and practical value. These motors have compact dimensions and a relatively high power density, as well as well-developed control and regulation facilities.

The results of the calculations show that when the motor is powered by a PWM inverter, the losses increase by ≈53–62% depending on the rotation speed compared to the case of power supply from a sinusoidal voltage source. Losses in the calculated area increase not proportionally with increasing rotational speed: with a 2-fold increase in speed, losses increase by ≈30%; with a 4-fold increase in speed, losses increase by ≈260%. At maximum rotational speeds of 20,000 rpm, the losses increase by ≈5.4 times compared to a speed of 3,000 rpm.

Locally, the largest losses are concentrated in the stator magnetic core on the teeth as the most saturated elements of the magnetic system. The total losses in these areas are ≈37% of the total calculated losses.

The losses and electromagnetic torque were estimated when using the rectangular shape of the PM. This will simplify and reduce the cost of manufacturing the final product, increase the level of unification in the manufacture of serial samples. Depending on the rotational speed, motor losses when using this motor shape are reduced by 20–36%. The value of electromagnetic torque, when using rectangular PMs, decreases by ≈22.5–30% depending on the rotation speed.

The results of the research provide practical recommendations for the design and operation of BWDMs to improve efficiency, operational reliability, losses and heating.

***Abstract*—This paper addresses the problem of efficient data transmission from wearable biomedical sensors via wireless communication channels in human motion biomechanics monitoring systems. A combined approach to sensor data compression is proposed, which includes preliminary octahedral transformation of accelerometer vectors followed by the use of the lossless Sprintz compression algorithm. This method accounts for the vector nature of the signal, reduces redundancy, and improves compression efficiency without significantly increasing the computational or memory load. Experimental evaluation demonstrated that the application of octahedral encoding reduces accelerometer data volume to 57% (compared to 84% without transformation), and the total transmitted data volume — to 61%, depending on the type of activity. The proposed approach is suitable for implementation on resource-constrained microcontroller-based platforms and is recommended for use in real-time systems.**

Keywords—biomechanics, wearable electronics, wireless sensors, ESP-Now, IMU, monitoring, octahedral encoding, Sprintz

I. Introduction

According to data from the World Health Organization, approximately 1.71 billion people — around 22% of the global population — suffer from musculoskeletal disorders, which lead to temporary or permanent limitations in physical activity, professional performance, and social interaction [1]. This category includes more than 150 different nosological forms characterized by damage to muscles, the skeletal system, joints, and surrounding connective tissues. These pathologies vary in their clinical course — from acute, short-term conditions such as fractures, sprains, and muscle strains accompanied by pain and functional impairment, to chronic diseases, including primary chronic lower back pain and osteoarthritis. Notably, lower back pain is among the most common medical issues over a lifetime, affecting up to 80% of individuals over the age of 35, leading to reduced productivity and quality of life. Under the current wartime conditions in Ukraine, there has been a significant increase in the number of limb amputations — according to estimates by Ottobock (Germany), a leading global manufacturer of prosthetics, the number of people with amputated limbs has reached approximately 50,000 [2].

Under these conditions, the use of biomechanical analysis methods for identifying and assessing functional impairments of the musculoskeletal system is of particular relevance, as it enables effective planning of therapeutic interventions. Modern non-invasive technologies are employed for this purpose, including electronic and electromechanical systems, smart clothing, exoskeletons, and other digital devices. In recent years, there has been a significant increase in the number of studies focused on the application of such technologies in biomedical contexts — for diagnostics, therapy, functional correction, and prevention of musculoskeletal disorders [3, 4, 5].

II. Review of Existing Solutions

Since the early 2000s, a large number of inertial measurement units (IMUs) have been developed, combining accelerometers and gyroscopes within a single device [5]. Key trends in the evolution of IMUs include miniaturization, reduced power consumption (down to microampere levels in low-power modes), and improved accuracy and stability of measurements. These characteristics have led to the widespread use of IMUs as wearable biomedical sensors [4], particularly for monitoring human motion biomechanics. A key feature of such sensors is the ability to transmit data wirelessly, which is essential given their typical placement on a freely moving human body. These sensors are integrated into a distributed monitoring system with a central device — a base station — that performs data collection, storage, and preliminary processing [6]. The central device can be a personal computer, a smartphone, or a specialized embedded computer. After data acquisition is complete, the recorded information is typically synchronized, resampled, and subjected to further analysis and processing.

A typical solution for establishing communication between sensors and the base station involves the use of one

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

of several wireless protocols, such as BLE/Bluetooth, Wi-Fi, Zigbee, ESP-Now [7, 8, 9], among others. One of the critical challenges in such systems is the synchronization of measurements from multiple sensors. A typical biomedical biomechanics diagnostic system consists of at least four sensors, which may, for example, be placed on the lower limbs of the patient. To ensure stable synchronization during wireless data transmission, a key parameter is the latency — the time required for a packet containing a time reference from the base station to reach the sensors. Therefore, it is advisable to select communication protocols with minimal transmission delay, such as ESP-Now [9]. However, such protocols are generally characterized by simplified connection mechanisms and limited bandwidth, despite operating on fixed frequency and channel width. This necessitates the implementation of additional mechanisms for managing time-division access to the channel (Time on Air, ToA) for sensor data transmission. At the same time, human biomechanics monitoring must be performed in real-time — sensor data are generated and transmitted continuously and must be stored without loss.

Given the aforementioned limitations, the task of reducing the volume of data transmitted via wireless communication channels becomes particularly relevant. Several approaches can be considered to address this challenge. One possible method is to reduce the sampling rate of the sensors. However, this approach significantly limits the potential for further analysis and detailed interpretation of the collected data, making it unsuitable for most applications involving precise monitoring of human motion biomechanics. Typical sampling rates in such systems range from 100 to 200 Hz, which provides sufficient temporal resolution for accurate assessment of dynamic movement parameters.

Another potential solution involves reducing the bit depth of the sensor-generated data [10]. However, this option also has substantial constraints: the typical bit resolution of signals is 12 to 16 bits per sample, which is the minimum required to preserve measurement accuracy and reliability. In the case of using two three-axis sensors (e.g., an accelerometer and a gyroscope), the total data volume from a single measurement reaches approximately 12 bytes. This imposes relatively high demands on the bandwidth of the communication channel, even when only a small number of sensors are used in the system.

At present, numerous sensor data compression methods have been developed, including well-known general-purpose algorithms such as Huffman coding [11], as well as less common approaches like block-dictionary encoding algorithms [12]. In addition, specialized compression methods are actively being developed. These differ from general-purpose techniques in that they require minimal computational resources for both encoding and decoding and are specifically designed for real-time processing of small data blocks [13], taking into account the characteristics of data generated by various types of sensors [14]. This study focuses on a lossless compression algorithm for sensor data, along with its software implementation. The proposed approach is based on the Sprintz method [15], which is designed for highly efficient compression of small time-series data blocks.

III. Data Encoding Algorithm

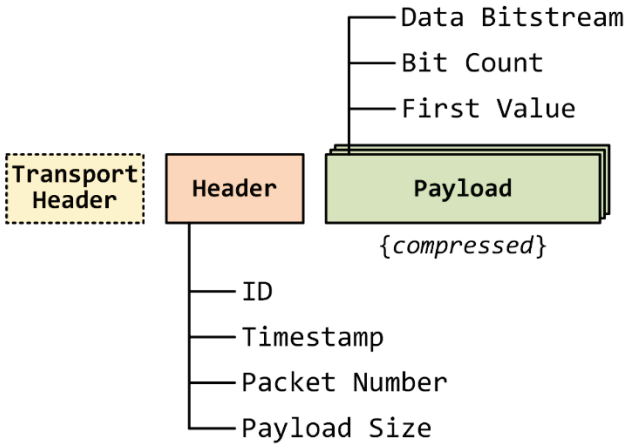
Sprintz is an efficient time series compression algorithm specifically designed for processing data from high-frequency sensors under constrained computational resources. This approach is particularly relevant for use in wearable devices and Internet of Things (IoT) systems. It offers fast compression and decompression while requiring minimal additional memory, which is critical for implementation on microcontroller-based platforms with limited resources. The algorithm is tailored for compressing time series represented as sequences of low-bitwidth integers (typically 8–16 bits), which closely corresponds to the data format generated by most sensor devices.

The method employs a predictor — either delta coding [16] or FIRE (Fast Integer Regression Estimator) — to forecast the next value based on a linear combination of previous samples. After prediction, the difference (prediction error) between the estimated and the actual value is calculated.

These differences typically have smaller amplitudes compared to the original values and exhibit reduced dynamic range, which significantly improves the efficiency of subsequent compression. In the next stage, the calculated differences are packed using bit-level encoding. For each fixed-size block of samples, the maximum number of bits required to represent the largest absolute value among the differences is determined. Based on this, all values within the block are encoded using a uniform bit width.

This block-based approach enables convenient integration of the algorithm into sensor data acquisition and transmission systems. In typical IMU (Inertial Measurement Unit) use cases, data are collected in a FIFO mode: values are stored in the sensor's internal memory and transferred to the microcontroller once a specified amount of data has been accumulated. This naturally forms a block of time-series data, which can be compressed independently. This independence is a key advantage, as the loss of a single block during transmission does not affect the decoding of others — the compression process does not rely on inter-block context.

After compression, each block for each channel follows a defined structure (Fig. 1), which includes the initial value of the sequence, the number of bits used for encoding, and the actual encoded differences aligned to byte boundaries.



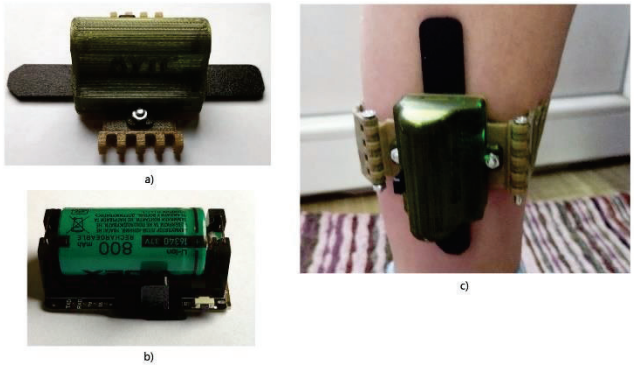


Fig. 1. Structure of compressed data blocks

IV. Implementation of the Algorithm Based on a Distributed Biomechanical Monitoring System

The algorithm was implemented within an existing monitoring system (Fig. 2), which is built using the BMI-160 IMU sensor module and an ESP32C3 microcontroller with an autonomous power supply. The system transmits data using the ESP-Now protocol in packet mode, with time-division access to the radio channel between sensors.

a) monitoring system in enclosure;
b) main board of the system with installed power supply;
c) method of attachment to the lower limb of a person.

Fig. 2. Wireless human biomechanics monitoring system

Each sensor module collects data from both the accelerometer and gyroscope, which are transmitted within a designated time slot along with time synchronization markers. The data rate from each sensor is 100 Hz, resulting in a total data throughput of approximately 1200 bytes per second per module. Experimental testing of the system was conducted during gait biomechanics analysis, with sensors mounted on the subject's lower limbs. The use of the Sprintz algorithm reduced the average volume of transmitted data to 75% of the original amount.

The transmitted data consist of the following components:

1. Packet headers (not subject to compression), accounting for approximately 8–10% of the total volume.
2. Accelerometer data — approximately 45%.
3. Gyroscope data — also approximately 45%.

Analysis of the compression efficiency for individual data streams showed that gyroscope data are compressed significantly more effectively, demonstrating an average compression ratio of approximately 63% during gait simulation at a walking speed of 3 km/h. In contrast, accelerometer data exhibit lower compression efficiency under the same conditions — only about 84%. A closer examination of the accelerometer data reveals that a significant portion is occupied by the gravity vector, while the acceleration components along the different axes are highly correlated. To improve compression efficiency, it is advisable to treat accelerometer data not as three independent channels, but rather as a single vector signal, from which both direction and magnitude can be derived. This vector-based model enables the application of transformations that reduce data redundancy and thus increase the overall compression ratio [17]. In particular, encoding the magnitude of the acceleration vector separately is beneficial, as it tends to change more slowly compared to the vector's orientation — providing opportunities for more aggressive compression without compromising accuracy.

Given the observed correlation among accelerometer data components and their inherent vector nature, it is appropriate to apply specialized spatial encoding methods that enable a more compact representation of the acceleration vector's orientation. One such approach is octahedral encoding [18], which was proposed for the efficient representation of normalized vectors in three-dimensional space.

The core idea of the method involves projecting a unit vector (normal) onto the surface of an octahedron, folding the octahedron onto a plane, and mapping the projection onto a unit square. This approach provides a uniform distribution of vector directions while reducing quantization artifacts typical of other spherical coordinate discretization methods [19]. The advantages of octahedral encoding include uniform value distribution, low computational cost for both encoding and decoding, and efficient storage in resource-constrained environments such as embedded sensor systems.

The proposed octahedral encoding technique is characterized by low computational complexity, making it well suited for implementation on systems with limited resources. Specifically, the encoding process requires only two reciprocal operations (rcp, i.e., 1/x), which can be efficiently executed using hardware arithmetic units available in most modern microcontrollers.

A key benefit of this method is the separation of the acceleration vector's magnitude from its orientation, allowing each component to be processed and compressed independently. Unlike some other spatial vector transformation methods, octahedral encoding does not increase the number of data channels and thus does not complicate the structure of transmitted packets.

To perform octahedral transformation, the following algorithm is used:

1) Vector magnitude calculation. Let $\vec{g} = (x, y, z)$ *be the acceleration vector. First, its Euclidean norm (magnitude) is calculated:*

$$\left|\vec{g}\right| = \sqrt{x^2 + y^2 + z^2}\ . \tag{1}$$

Alternatively, to reduce computational complexity, the Manhattan norm can be used as an approximation:

$$S = |x| + |y| + |z|$$

2) Vector normalization. The vector is normalized to unit length:

$$\vec{g}_{norm} = \left(\frac{x}{\left|\vec{g}\right|}, \frac{y}{\left|\vec{g}\right|}, \frac{z}{\left|\vec{g}\right|} \right) \tag{2}$$

3) Projection to a plane (dimensionality reduction). Since the vector is normalized, its orientation can be represented in two dimensions by projecting it onto a plane using octahedral transformation:

$$u = \frac{x}{S},\ v = \frac{y}{S} \tag{3}$$

4) Reflection to preserve direction (sign of z). If the normalized component is negative z < 0, reflection is applied to ensure the orientation can be uniquely restored:

$$u' = \left(1 - |v|\right) \cdot \text{sign}(u),\ v' = \left(1 - |u|\right) \cdot \text{sign}(v) \tag{4}$$

5) Quantization of the result. The resulting coordinates (u', v') *are scaled and quantized into a discrete* ***N*×*N*** *grid, for example, 256×256 (corresponding to 8-bit representation for each coordinate):*

$$u_q = \text{round}\left(\frac{u'+1}{2} \cdot (\text{N}-1)\right), \tag{5}$$

$$v_q = \text{round}\left(\frac{v'+1}{2} \cdot (\text{N}-1)\right) \tag{6}$$

After encoding, the vector magnitude is stored separately, and the direction is represented as a pair of quantized coordinates . This approach enables a significant reduction in the volume of data for storage and transmission without substantial loss of accuracy.

Experimental evaluation of the effectiveness of this approach was conducted under conditions similar to the previous test — specifically, during simulated human walking at a speed of 3 km/h.

The obtained results demonstrate the following:

1) the total volume of transmitted data after transformation and compression was reduced to approximately 61% of the original (uncompressed) size;

2) the accelerometer data component, after applying octahedral encoding, was compressed to 57% of its original size — a significant improvement compared to the previous value of 84% without transformation.

The results of data compression for various types of user physical activity are presented in Table 1, illustrating how compression efficiency varies depending on the nature of the movement.

TABLE I. SENSOR DATA COMPRESSION RESULTS FOR DIFFERENT ACTIVITY MEASUREMENTS

Activity	Sprinz			Octahedral encoding	
	Acc, %	Gyro, %	Total, %	Acc, %	Total, %
Slow walk	83.8	63.0	74.5	56.3	61.0
Walk	83.6	66.3	76.0	57.7	63.5
Run	95.3	77.9	87.1	66.5	73.3
Sports exercises	97.5	80.6	89.5	70.2	76.4

V. DISCUSSION

Analysis of the obtained results reveals a consistent trend: as the intensity of physical activity increases — from normal walking to dynamic exercise — the amplitude and variability of sensor signals also increase. Consequently, compression efficiency decreases due to greater difficulty in prediction and higher data entropy.

Nevertheless, the application of octahedral encoding as a preprocessing step for accelerometer data enables a substantial reduction in the overall volume of transmitted information. Even in the least favorable scenario, a 29.8% data size reduction was achieved, which is a significant result for resource-constrained systems, particularly embedded and wearable sensor modules.

VI. CONCLUSIONS

The results of this study demonstrate that the application of octahedral encoding significantly reduces the volume of data transmitted from accelerometers in human motion biomechanics monitoring systems. Specifically, under normal walking conditions, the data size was reduced from 84% to 57%, which represents a substantial improvement.

The implementation of both the octahedral transformation and the subsequent lossless compression algorithm (Sprintz) requires no significant additional computational or memory resources from the microcontroller, making the proposed approach well suited for integration into resource-constrained sensor devices. The total volume of transmitted data was reduced to 61–77% depending on the type of physical activity, confirming the method's effectiveness in real-world conditions.

Future research should focus on the exploration of lossy compression methods, which have the potential to achieve even greater data reduction, as well as the implementation of preprocessing and filtering directly on the sensor module. Evaluating the impact of such preprocessing on the efficiency of various compression techniques is also recommended.

***Abstract*— The drying process in industrial chambers is critical for optimizing energy efficiency and product quality, but presents complex control challenges. This study addresses the optimal control problem for a drying chamber model, aiming to minimize energy consumption. A mathematical model of the drying process is developed, and optimal control strategies are derived for specific time intervals. The results demonstrate the potential of advanced control techniques to enhance drying efficiency, providing practical benefits for industrial applications and guiding future research into real-time control implementations.**

Keywords—automatic control system, transfer function, mathematical model, drying chamber, optimization

I. Introduction

Optimal control of drying chambers is critical across industries where drying processes are integral. The drying chamber is a key component in these processes, and controlling it optimally offers many benefits. Optimal control of the drying chamber is **relevant** for achieving energy efficiency, maintaining product quality, optimizing process time, ensuring uniformity, prolonging equipment life, and reducing the environmental impact of drying processes in various industries. The drying process and batch type drying chambers and solving the optimal control problem for the drying chamber using the second order model are considered. The **purpose** of the article is to optimize the drying processes of capillary-porous materials. A batch drying chamber was chosen, which allows better quality and flexibility to set drying modes in order to achieve the most optimal parameters. An analysis of existing technical solutions was carried out this topic. The solution of optimization tasks with the use of the second order model is considered. The optimal solution of this problem in a classical way, using the Hamiltonian was found. According to **the results** of the study, graph of optimal movement trajectory was obtained. The optimal movement trajectory for the control object is three-interval process.

Today, capillary drying is most often carried out in drying chambers. Drying takes place in accordance with all known laws of physics [1]. What the faster the material receives the energy needed to evaporate the liquid, the faster it is dries [2]. Wood drying is the stage where more energy is consumed during wood processing. An incorrect drying process generates cracking problems, rupture of the cellular structure of the wood, folding in the piece [3]. In the industrial drying various drying defects still occur, which include uneven moisture content between and within boards, board distortion, residual drying stresses that may induce internal and external checking, and wood collapse [4]. Natural drying is more time-consuming and does not give the required moisture percentage [5]. Therefore, artificial drying is used. It takes place in batch or continuous chambers. All types of dryers, irrespective of differences in their structure, perform loading, drying, cooling, and unloading operations. In batch dryers, these operations are separated in time and conducted in a specified order [6]. There are several types of drying chambers, but the drying chamber is considered in this work batch dryer chamber. These chambers are much shorter than others and during drying throughout the chamber constant environment parameters are supported. In such a chamber, the material can be dried up to of any required final humidity [7]. At the moment, the equipment is drying cameras are equipped with automatic humidity control systems, ventilation control etc. Such drying chambers use 20% less energy.

II. Overview of existing technical solutions

PI and PID controllers were one of the first regulators. They have proven their effectiveness in managing various processes. The use of such controllers does not require knowledge of the exact process model, so they are effective in managing industrial processes, the mathematical models of which are quite complex. PI and PID controllers are built on the basis of classical control theory and are easy to understand [8]. Establishing relationships between parameters and managing system actions can be carried out by practical engineers and operators. In addition, several tuning methods for PI and PID controllers have been developed over the past decades. A more modern method of automatic adjustment of PI and PID controllers was proposed by Nishikawa in [9]. It requires an input test signal to evaluate process parameters. Optimal values of PI and PID parameters are achieved by minimizing the weighted integral of the quadratic error. However, along with the above advantages, PI and PID controllers have a number of disadvantages. Yes, if the process operating point changes, the controller parameters must be manually readjusted to obtain the new optimal setting. Adjustment must be performed by an experienced operator. For systems with interacting loops, this procedure can be complex and time-consuming. And even if an energy-optimal tracking controller exists, it is only as efficient as the reference trajectory that it is tracking [10]. PI and PID controllers can be effectively applied to optimal control by tuning their parameters to minimize a cost function that balances error, control effort, and dynamic performance. PID is better for dynamic systems requiring fast response and stability. For practical implementation, we have to model the system, define a cost function, and use simulation or optimization tools to find the best gains. PID controllers can be used as a low-level controller within an MPC framework, where MPC computes optimal setpoints or gains over a horizon.

One of the modern approaches to the analysis and synthesis of control systems based on mathematical optimization methods is the theory of control of dynamic objects using predictive models. In [11] and [12], the algorithm of this method is very well described, but the

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

implementation of the method is not shown on specific examples, including in control systems.

In design and optimization of drying processes, there is a great need for stable and reliable models to quantify and predict drying rates and drying times with a satisfying accuracy [13].

The steaming process during drying of capillary-porous materials should be optimized using a second-order model. In [14] the solution to the problem optimization with constraints is shown very well. At the same time, the solution of this problem is considered in a classical way, using the Hamiltonian [15].

III. Solving the Optimal Control Problem for the Second-Order Model

The mathematical models in the drying process have been studied under different conditions and configurations i.e., porous media and shrinkage [16]. But as a predictive model for the drying chamber, we will consider a second-order control object with a transfer function [17]:

$$K_2(s) = \frac{4}{3.7s+1} \cdot \frac{42}{1.3s+1} = \frac{168}{4.81s^2+5s+1} \quad (1)$$

A second-order differential equation models the dynamics of key variables, such as temperature or moisture content, with control inputs like heat or airflow rate.

The solution to these problems can be characterized by the Pontryagin's maximum principle [18]. Pontryagin's Maximum Principle is a fundamental tool in optimal control theory used to find the control inputs that optimize a performance index for dynamic systems. It provides a rigorous mathematical approach to optimal control by defining conditions under which a control input optimizes a performance criterion. PMP leverages the system's dynamics to derive analytically grounded control laws, making it well-suited for the behavior of drying processes. Let's find the optimal energy-saving control for this model using the classical method.

The differential equation corresponding to the transfer function (1) will have the following form:

$$3.7 \cdot 1.3\frac{d^2\theta}{dt^2} + (3.7 + 1.3)\frac{d\theta}{dt} + \theta = 168 \cdot U, \quad (2)$$

where the controlling influence is limited $0 \le U \le 1$. In [19] there are some examples of such problems are given, including extensions of the linear-quadratic controller with tight and possibly state-dependent control constraints, as well as piecewise linear-quadratic constraints. Let's write equation (2) as a system of two equations:

$$\begin{cases} 3.7\frac{d\theta_1}{dt} + \theta_1 = 168 \cdot U; \\ 1.3\frac{d\theta}{dt} + \theta = \theta_1. \end{cases} \quad (3)$$

We reduce the system (3) to its normal form:

$$\begin{cases} \frac{d\theta_1}{dt}_1 = \frac{1}{3,7} \cdot (168 \cdot U - \theta_1) = f_1; \\ \frac{d\theta}{dt} = \frac{1}{1.3} \cdot (\theta_1 - \theta) = f_2. \end{cases} \quad (4)$$

Using (4), let's make the equation for the coupled variables for ψ

$$\begin{cases} \frac{d\psi_1}{dt} = -\left[\frac{\partial f_1}{\partial \theta_1} \cdot \psi_1 + \frac{\partial f_2}{\partial \theta_1} \cdot \psi_2\right] = \\ = \frac{1}{3,7} \cdot \psi_1 - \frac{1}{1,3} \cdot \psi_2; \\ \frac{d\psi_2}{dt} = -\left[\frac{\partial f_1}{\partial \theta} \cdot \psi_1 + \frac{\partial f_2}{\partial \theta} \cdot \psi_2\right] = \\ = \frac{1}{1,3} \cdot \psi_2. \end{cases} \quad (5)$$

Let's find a solution for ψ_1 and ψ_2:

$$\begin{cases} \psi_2 = \mathrm{C}_0 \cdot e^{\frac{-t}{1.3}}; \\ \psi_1 == C_1 \cdot e^{\frac{t}{1.3}} - C_2 \cdot e^{\frac{t}{3.7}}. \end{cases} \quad (6)$$

Let's add the Hamiltonian:

$$H = \psi_1 \cdot \frac{1}{3.7} \cdot (168 \cdot U - \theta_1) + \psi_2 \cdot \frac{1}{1.3} \cdot (\theta_1 - \theta) \quad (7)$$

Considering only the term that depends on U, and taking into account the values of ψ_1 and $\psi_2$we obtain from (6):

$$H' = (C_1 \cdot e^{\frac{t}{1.3}} - C_2 \cdot e^{\frac{t}{3.7}}) \cdot 45.41 \cdot U. \quad (8)$$

In order for the Hamiltonian to have a maximum value as required by the maximum principle [20], it is necessary to observe equality $U = U_{max}$ and ensure that the sign changes U_{max} as many times as it is changed by the function ψ_1. Otherwise, you can write that

$$H' = (C_1 \cdot e^{\frac{t}{1.3}} - C_2 \cdot e^{\frac{t}{3.7}}) \cdot 45.41 \cdot U_{max} \quad (9)$$

that is, control will be determined by the ratio

$$U(t) = \sigma \cdot U_{max}$$

where:

$$\sigma = sign(C_1 \cdot e^{\frac{t}{1.3}} - C_2 \cdot e^{\frac{t}{3.7}}) \quad (10)$$

Since the function $\psi_1(t)$ changes its sign at any values $C_1$and C_2 no more than once per time interval, then the law of change $U(t) = \sigma \cdot U_{max}$ where $\sigma = \pm 1$, and taking into account the restriction $0 \le U \le 1$ is obtained $\sigma = +1{,}0$.

Let's determine the moments of switching t_1 and t_2, and also construct the optimal transitional process. The switching moments are determined by the optimal control function:

$$t_i = f_i(\alpha_1, \ldots, \alpha_n, \overline{x}_0, \overline{x}_n, U_{max}) \quad (11)$$

To find this function, we use the method of joining differential equations with a sign-changing right-hand side, write down the solution of equation (2) on the first interval:

$$\theta(t) = C_0' + C_1' \cdot e^{\frac{-t}{3.7}} + C_2' \cdot e^{\frac{-t}{1.3}}, \quad (12)$$

where $C_0' = 168 \cdot U$, C_1' and C_2' constant integrations on the first control interval.

Using the initial conditions for $t = 0$, $\theta = 0$ and $\dot{\theta} = 0$, and we write down the system of equations for determining the constants of integration:

$$\begin{cases} 168 \cdot U + C_1' + C_2' = 0; \\ -0.27 \cdot C_1' - 0.77 \cdot C_2' = 0. \end{cases} \quad (13)$$

Using Kramer's method, we will find the solution of the system (13)

$$\Delta = \begin{vmatrix} 1 & 1 \\ -0.27 & -0.77 \end{vmatrix} = -0.5, \quad (14)$$

$$\Delta_1 = \begin{vmatrix} -168 \cdot U & 1 \\ 0 & -0.77 \end{vmatrix} = 129.36 \cdot U, \quad (15)$$

Then

$$C_1' = \frac{\Delta_1}{\Delta} = \frac{129.36 \cdot U}{-0.5} = -258.72 \cdot U \quad (16)$$

$$C_2' = \frac{\Delta_2}{\Delta} = \frac{-45.36 \cdot U}{-0.5} = 90.72 \cdot U \quad (17)$$

Therefore, the solution to equation (2) in the first control interval will be written as follows:

$$\theta(t) = 168 \cdot U - 258.72 \cdot U \cdot e^{\frac{-t}{3.7}} + 90.72 \cdot U \cdot e^{\frac{-t}{1.3}} \quad (18)$$

Let's write the solution of the differential equation (2) on the second control interval:

$$\begin{cases} \theta(t) = C_1'' \cdot e^{\frac{-t}{3.7}} + C_2'' \cdot e^{\frac{-t}{1.3}} \\ \dot{\theta}(t) = -0.27 \cdot C_1'' \cdot e^{\frac{-t}{3.7}} - 0.77 \cdot C_2'' \cdot e^{\frac{-t}{1.3}} \end{cases} \quad (19)$$

Taking into account the final conditions at $t = t_2$, $\theta = \theta_n$, $\dot{\theta} = 0$ determine the constant integrations on the second interval according to Kramer's method:

$$\begin{cases} \theta_n = C_1'' \cdot e^{\frac{-t}{3.7}} + C_2'' \cdot e^{\frac{-t}{1.3}} \\ 0 = -0.27 \cdot C_1'' \cdot e^{\frac{-t}{3.7}} - 0.77 \cdot C_2'' \cdot e^{\frac{-t}{1.3}} \end{cases} \quad (20)$$

$$\Delta' = \begin{vmatrix} e^{\frac{-t}{3.7}} & e^{\frac{-t}{1.3}} \\ -0.27 \cdot e^{\frac{-t}{3.7}} & -0.77 \cdot e^{\frac{-t}{1.3}} \end{vmatrix} \quad (21)$$

$$\Delta_1' = \begin{vmatrix} \theta_n & e^{\frac{-t}{1.3}} \\ 0 & -0.77 \cdot e^{\frac{-t}{1.3}} \end{vmatrix} \quad (22)$$

$$\Delta_2' = \begin{vmatrix} e^{\frac{-t}{3.7}} & \theta_n \\ -0.27 \cdot e^{\frac{-t}{3.7}} & 0 \end{vmatrix} \quad (23)$$

Then

$$C_1'' = \frac{\Delta_1'}{\Delta'} = 1.54 \cdot \theta_n \cdot e^{0.27t} \quad (24)$$

$$C_2'' = \frac{\Delta_2'}{\Delta'} = -0.54 \cdot \theta_n \cdot e^{0.77t} \quad (25)$$

We will connect solutions at the moment of time t_1:

$$C_0' + C_1' \cdot e^{\frac{-t}{3.7}} + C_2' \cdot e^{\frac{-t}{1.3}} = = C_1'' \cdot e^{\frac{-t}{3.7}} + C_2'' \cdot e^{\frac{-t}{1.3}}$$

$$-0.27 \cdot C_1' \cdot e^{\frac{-t}{3.7}} - 0.77 \cdot C_2' \cdot e^{\frac{-t}{1.3}} = = -0.27 \cdot C_1'' \cdot e^{\frac{-t}{3.7}} - 0.77 \cdot C_2'' \cdot e^{\frac{-t}{1.3}} \quad (26)$$

$$\begin{cases} (C_1' - C_1'') \cdot e^{\frac{-t}{3.7}} + (C_2' - C_2'') \cdot e^{\frac{-t}{1.3}} = -168U \\ 0.27 \cdot (C_1' - C_1'') e^{\frac{-t}{3.7}} + 0{,}77 \cdot (C_2' - C_2'') e^{\frac{-t}{1.3}} = 0 \end{cases} \quad (27)$$

Including the constant integrations found earlier, we obtain a system of equations for determining the switching moments:

$$\begin{cases} \frac{\theta_n}{168 \cdot U} e^{0.27t_2} - e^{0.27t_1} + 1 = 0 \\ \frac{\theta_n}{168 \cdot U} e^{0.77t_2} - e^{0.77t_1} + 1 = 0 \end{cases} \quad (28)$$

According to the (28) the moments of time for various are calculated and listed in Table 1.

TABLE I. THE MOMENTS OF TIME FOR VARIOUS

θ_n	t_1	t_2
10	0.3887	2.2975
20	0.7805	2.5123
30	1.1786	2.7453
40	1.5851	2.9857
50	2.0081	3.2712
60	2.4483	3.5714
70	2.9127	3.9042
80	3.4085	4.2749
90	3.9456	4.6925
100	4.5883	5.2133
110	5.2057	5.7339

The control algorithm and transition process for $\theta = 100°$ for the control object (2) are shown in the graph (Fig.1)

As can be seen, the optimal control will be three-interval and can be easily calculated using electronic computing machines. In the future, this model can be used to predict higher-order systems. This requires extending the lumped parameter model to include thermal inertia and moisture diffusion dynamics. The model then includes a second-order temperature response (to account for heat accumulation) and a delayed humidity response (to model diffusion delays). The second-order temperature response causes overshoot, and the delayed humidity response causes oscillatory control actions. While PID mitigates some of the problems with derivative action, both methods rely on heuristic tuning, not optimizing energy use in complex systems. Higher-order systems make the model more realistic, but increase control complexity.

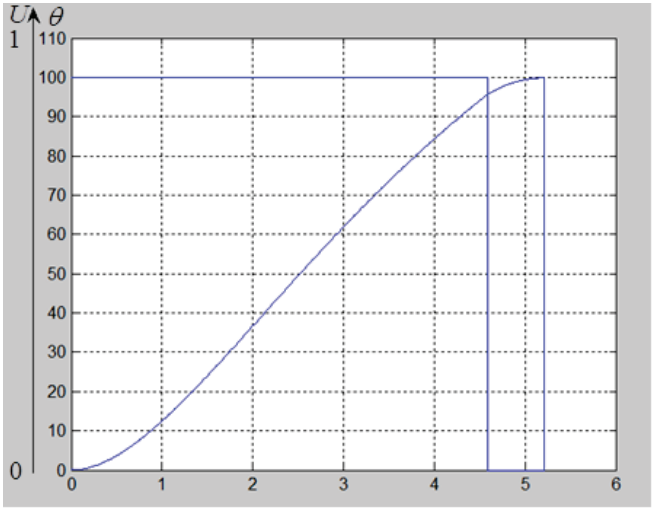

Fig. 1. The optimal movement trajectory for the control object.

Pontryagin's maximum principle for a drying chamber allows finding an optimal control that minimizes the drying time or energy consumption. For simple models, optimal control is often marginal, as we can see from the above, but in

real problems, numerical methods are required due to nonlinearity and additional constraints. The principle is poorly suited for systems with random disturbances, such as non-uniform material moisture in a drying chamber, because it was designed for deterministic systems. This maximum principle guarantees the absence of optimality conditions, not sufficient ones. In nonlinear problems, it is possible to have local optimality that are not globally optimal.

Using AI in modeling drying chambers enables the development of highly accurate second-order models by leveraging machine learning to analyze complex drying dynamics, such as moisture content and temperature variations. Neural networks can be trained on historical and real-time data to predict optimal parameters, accounting for nonlinearities and material-specific properties like those of capillary-porous materials. Current developments in AI offer transformative potential for solving problems in modeling, predicting, and controlling drying chambers dynamics. Future research could improve predictive modeling based on machine learning to predict temperature and humidity trajectories under different conditions. An example of a scheme that can use our model made in this work is shown in Fig.2.

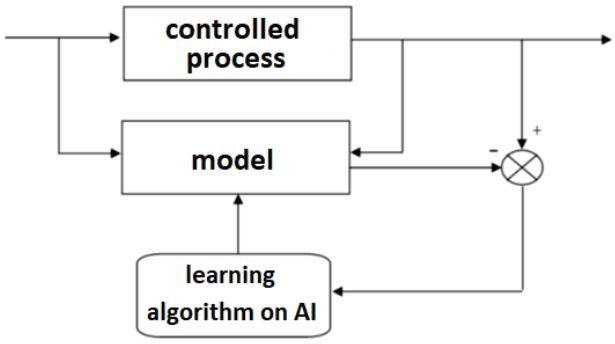

Fig. 2. The scheme for model with AI.

AI could enable adaptive control by processing sensor data in real time, adjusting for disturbances such as material changes or environmental changes.

Furthermore, AI can optimize the second-order model by identifying key parameters through techniques like sensitivity analysis, ensuring robust performance under varying conditions. It also facilitates the real-time adjustment of control inputs by continuously learning from sensor data, enhancing the practicality of implementing optimal control strategies. This capability makes AI a transformative approach for advancing drying chamber research and industrial applications.

CONCLUSIONS

1. Choosing the right method is the most effective and practical tool in solving the problem of optimal management.

2. The optimal control was found, which minimizes the consumption of the heat carrier during the heating stage of the material being dried under the given restrictions on the control influence.

3. Optimal movement trajectories of the regulated quantity for mathematical models of the second order is constructed.

***Abstract*—Digital images are widely used in many technologies that are an integral part of various systems. Compared to other types of data, their specific feature is a relatively large size that restricts the use of different machine learning (ML) and computer vision (CV) methods. A large data processing time and image spatial complexity become additional blockers for applying many ML and CV algorithms if real-time results are required or if the main computations must be performed on autonomous systems with limited capabilities. For this reason, the problem of the development of a compact image representation, which contains features useful in ML/CV techniques, is relevant. In this paper, we consider the use of discrete atomic transform (DAT) based on atomic functions for solving this problem. Our previous investigation had proven that DAT provided a combination of data compression and encryption features. This research shows that DAT representation is ML/CV-oriented with respect to image classification using state-of-the-art convolutional neural networks. Thus, its application in different methods for image analysis is promising.**

Keywords—image representation, atomic function, discrete atomic transform, atomic embeddings, classification, convolutional neural networks

I. Introduction

Digital images are widely used in many fields including ecological monitoring [1], precision agriculture [2], urban planning [3], disaster management [4], oceanography [5], climate sciences [6], archeology [7], military and defense [8], etc. Similarly to other types of big data, their specific feature is a large size that leads to huge memory, time, and traffic expenses due to the ability of modern sensors to produce images with tens of millions of pixels. In order to reduce these costs, image compression algorithms are applied [9]. Such methods provide a reduction of the resources required for storing, processing, and transferring images via networks and communication lines. Another significant challenge is the limitations of applying different machine learning (ML) and computer vision (CV) algorithms.

Remote sensing (RS) images are a key component of intelligent systems that implement a wide range of ML/CV techniques [10]. These methods extract features and transform them into smart data. Often, they manipulate raw image data that leads to significant computational expenses required for both analysis and decompression. To perform these computations, different strategies are applied [11]. They involve the usage of graphics and tensor processing units, cloud and distributed computing, etc. However, there exist several significant limitations. First, for autonomous systems and edge devices, special hardware cannot be utilized, especially due to the absence of a required power supply. Next, remote computing increases the load of networks. Furthermore, transferring large amounts of data may not be possible due to the communication channels' bandwidth limitations or interference. For this reason, approaches that leverage machine learning at the edge are adopted [12]. Regardless of the way applied, significant computational resource expenses are challenging. And the problem of their reduction is of particular relevance.

To reduce computation required for image processing and analyzing we propose the use of image representation that combines the following attractive properties:

- Data compression: the decrease of memory expenses required for storing an image.
- Features' compactness: the decomposition of image content into a structured set of small-sized blocks containing features referred to the whole data.

In general, we call a representation ML/CV-oriented if an application of ML/CV methods to a limited number of such blocks provides near the same results as their application to the (full-size) original image. In this context, "near the same results" means minor degradation of methods effectiveness in terms of appropriate metrics.

A lot of data compression methods have been developed recently [11]. Some of them are general-purpose algorithms and can be applied to any data. Moreover, there are specialized techniques that can be used for compressing data of a specific type, in particular, digital images [13]. Generally, they provide better compression. The main goal in the development of both algorithm types was to ensure high memory savings in combination with an acceptable computational complexity. At that time, the majority of analysis algorithms used raw image data [14, 15]. For this reason, a design of ML/CV-oriented representations was not the focus of the research and development.

In this paper, we consider image representation by atomic functions (AFs) [16]. It is based on discrete atomic transform (DAT) that is constructed using the function $up_s(x)$ [17]. It is this combination that provides rapid data expansion and efficient image compression. In [18], it is shown that lossy compression by DAT has a minor impact on the performance

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

of a set of state-of-the-art image classifiers. Hence, the following hypothesis is plausible: the image data representation by DAT is ML/CV-oriented. Our aim is to prove this statement with respect to classification using convolutional neural networks (CNNs). We explore image previews produced by DAT in the MobileNetV2, VGG16, VGG19, ResNet50, NASNetMobile, and NASNetLarge [19] classifiers, which constitutes the novelty of this research. We show that, when applying these algorithms to a source image and its preview, nearly the same results are obtained. This is the main contribution.

II. Task Formulation and Solution Methods Choice

Image classification is one of the main tasks of CV [15]. A lot of methods for solving this problem has been recently developed. The application of deep CNNs is among them and has shown high performance [19]. In general, a CNN-based classifier takes an input image, extracts high-level features and predicts its class. An input of such models is a matrix of a fixed size that contains raw pixel data. Therefore, in order to apply some model to a given image, the following steps are performed. First, since images are usually stored in a compressed format, a decompression procedure is applied. Second, a decompressed image is resized to meet CNN input size requirements. This implies that additional computational resources are needed. We note that modern cameras provide images with a great number of pixels. So, the preprocessing step, which is applied before data class prediction, might be time consuming, which might be a blocker for applying CNN-based classifiers in real time, especially in embedded devices. Thus, the preprocessing expenses reduction task is relevant. We propose to solve it using image representation by atomic functions.

Fig. 1 describes the scheme of discrete atomic compression (DAC) of 24-bit full color digital images [16, 20]. Its first step performs the RGB-to-YCrCb color space conversion and computes matrices of luma (Y) and chroma components (Cr, Cb). Then, the DAT transform is applied to each of them. Further, elements of the obtained matrices of DAT coefficients are quantized and, then, encoded using a combination of Golomb codes and context adaptive binary arithmetic coding.

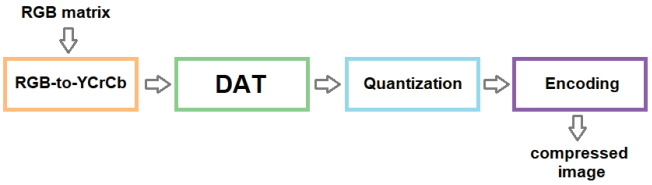

Fig. 1. Discrete atomic compression of 24-bit full color images.

The DAC produces a file with compressed data. We suggest to extract an image preview from this file without a complete decompression. Further, this preview, which is supposed to be an image of significantly smaller size than a source one, is resized and, then, is passed to a classifier. It is clear that, in general, the computed prediction may not coincide with the prediction obtained for a source. So, the following question naturally raises: on average, what percentage of result similarity is ensured? To answer this question, we consider a set of models that includes the following CNNs: MobileNetV2, VGG16, VGG19, ResNet50, NASNetMobile, and NASNetLarge. Currently, we use models with trained weights from the TensorFlow Keras collection [21]. These models implement different architectures. Table 1 illustrates their main parameters.

TABLE I. Models' Characteristics

Model	Depth	Number of Parameters (millions)
MobileNetV2	55	4.3
VGG16	16	138.4
VGG19	19	143.7
ResNet50	107	25.6
NASNetMobile	389	5.3
NASNetLarge	533	88.9

Further, we apply the considered models to a set of digital images and their previews obtained from DAC files. For each pair, we compare top five predicted classes with the highest probabilities. Moreover, to provide a baseline, we perform the same analysis for a discrete transform based on the Haar wavelet [22, 23].

III. Image Representation by Atomic Functions

DAT is a core of the DAC algorithm. It is based on the following expansion [24]:

$$f(x) = \sum_{k=1}^{m+1} \sum_j \omega_j^{[k]} w_k \left(x - \frac{j}{2^{m+1}}\right),$$

where m is positive integer, $\{w_k(x)\}_{k=1,\dots,m+1}$ is a system of atomic wavelets constructed using the atomic function

$$up_s(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{itx} \prod_{k=1}^{\infty} \frac{\sin^2\left(st(2s)^{-k}\right)}{s^2 t(2s)^{-k} \sin\left(t(2s)^{-k}\right)} dt, s \in N,$$

and $\Omega = \left\{\omega_j^{[k]}\right\}$ is a system of atomic wavelet coefficients.

If $f(x)$ represents a discrete data $D = (d_1, \dots, d_n)$, then the transform, which maps D to Ω, is called the array DAT.

The matrix DAT is defined as follows. Let M be a given matrix. First, the array DAT is applied to each row of M. Then, it is applied to each column of the matrix obtained at the previous step. An output is a block-structured matrix of DAT coefficients B. Fig.2 illustrates this procedure.

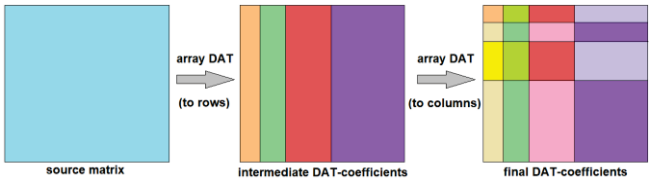

Fig. 2. Discrete atomic transform of a matrix.

By design, B consists of blocks: $B = \left(B_{ij}\right)_{i,j=1}^{m+1}$. Their total number is $(m+1)(m+1)$. Each of them contains DAT coefficients corresponding to a certain spatial frequency band. From the properties of atomic wavelets [24], it follows that elements of the block B_{00} represent an aggregation of the matrix M. In terms of digital images, B_{00} is a preview or small copy of an image given by M. If h and w are, respectively, the height and width of M, then B_{00} is a matrix of the size $\frac{h}{2^m} \times \frac{w}{2^m}$. Blocks of atomic wavelet coefficients constitute image representation by atomic functions.

The matrix DAT has two hyperparameters that specify its settings: s and m. These entities define the applied atomic function and the depth of the wavelet transform, respectively.

In our previous research [20], it has been shown that the DAC based on DAT with $s = 32$ and $m = 5$ provides a combination of high compression ratio with low loss of quality measured by maximum absolute deviation (MAD) and peak signal-to-noise-ratio (PSNR). Moreover, the paper [18] proves that the produced distortions have minor effect on the efficiency of the MobileNetV2, VGG16, VGG19, ResNet50, NASNetMobile, and NASNetLarge classifiers. Here, we use the same hyperparameters.

It is clear that the size of the block B_{00} decreases exponentially with respect to the growth of the depth m. Therefore, an image preview preprocessing, which is needed before an application of CNNs, requires significantly less computations than preprocessing of the corresponding source image. Besides, due to good approximation properties of atomic functions and, hence, atomic wavelets [17], a preview might preserve image features sufficient for classification of a source. Further, we call an image preview produced by the blocks B_{00} atomic. Fig. 3 shows an example.

Fig. 3. Digital photo preview produced by the blocks B_{00} of atomic wavelets. A true size image is given. Preview: 256 × 193 pixels, 144 KB (raw). Source: 8157×6117 pixels, 4.31 MB (JPEG).

IV. Image Classification Using Atomic Preview

To explore the efficiency of image classification by its atomic preview, we consider a set of 130 high quality digital photos given in the JPEG format. The total memory size of JPEG files is 1.35 GB. Raw data require 19.55 GB. Each sample has large height and width. The average number of pixels is 50 million. We compress these data by DAC with settings that provide mean PSNR = 40 dB. We obtain a set of DAC files of the total memory size of 823 MB. The minimum value of PSNR is 35.15 dB. Then, we obtain atomic previews. Fig. 3 shows an example. Next, we apply the MobileNetV2, VGG16, VGG19, ResNet50, NASNetMobile, and NASNetLarge models to each source image and its preview. An output of these models is a vector probabilities (each component represents the likelihood of the analyzed image belonging to a particular class). Further, we compare top five predictions with the highest probabilities for a source and a preview, and compute the similarity, which is the percentage of equal elements. Finally, we evaluate its mean value over all sample images. In addition, we obtain the percentage of cases, when the best predicted classes for a source image and its preview coincide. Also, we perform the same analysis for previews obtained using the Haar wavelet of the depth 5.

Tables 2, 3 present the obtained results. We note that, actually, the aggregated results are given. Detailed results for each image analysis can be found at the following link: https://drive.google.com/drive/folders/14DBoS9JskIgS3yOZ0ftccc7OXzv6VFQo?usp=sharing. The considered images and their atomic previews are available there. Fig. 4 – 7 provide a visualization.

TABLE II. The Average Percentage of Similar Classes, %

Model	Atomic preview	Haar preview
MobileNetV2	84.00	80.92
NASNetLarge	86.00	84.77
NASNetMobile	87.23	87.85
ResNet50	90.15	86.46
VGG16	92.00	90.15
VGG19	92.92	91.69

TABLE III. The Best Class Similarity, %

Model	Atomic preview	Haar preview
MobileNetV2	86.92	76.15
NASNetLarge	83.85	84.62
NASNetMobile	86.92	89.23
ResNet50	90.00	86.15
VGG16	90.77	81.54
VGG19	95.38	87.69

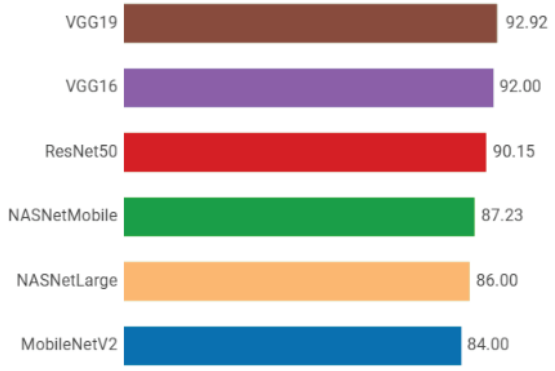

Fig. 4. The average percentage of similar classes: atomic preview.

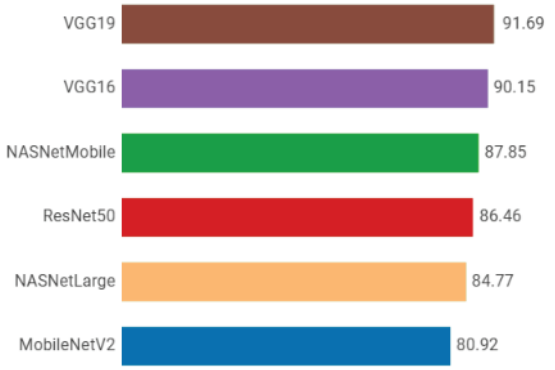

Fig. 5. The average percentage of similar classes: Haar preview.

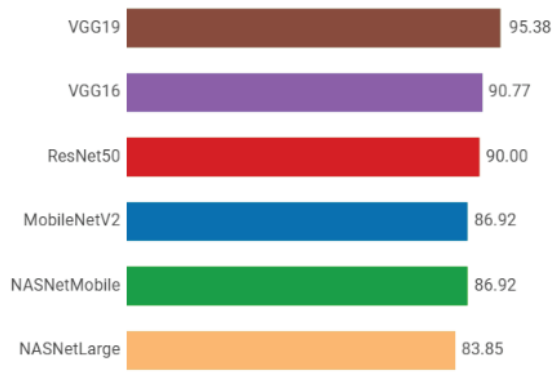

Fig. 6. The best class similarity (%): atomic preview.

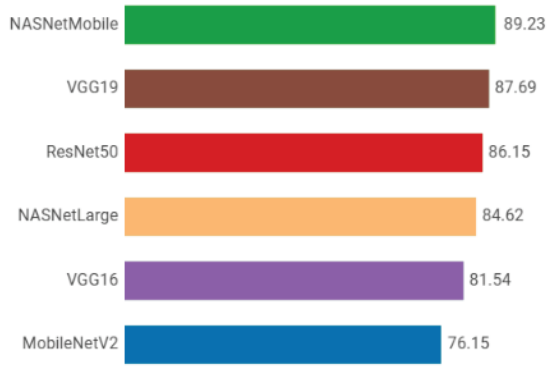

Fig. 7. The best class similarity (%): Haar preview.

In addition, Fig. 8 shows the correlation plot indicating the dependencies between the evaluated metrics and the model's characteristics given in Table 1.

	layers	parameters
similar classes (atomic preview)	-0.47	0.81
best class (atomic preview)	-0.67	0.76
similar classes (Haar preview)	-0.15	0.91
best class (Haar preview)	0.50	0.38

Fig. 8. The correlations between the model's characteristics and the performance metrics.

Considering the mean percentage of similar classes, we see the following:

- The use of both atomic and Haar previews for classifying a source image ensures a high match of top five predicted classes. On average, at least four of them are similar.
- In the most cases, atomic preview provides better results than Haar preview. The only exception is the NASNetMobile model. Although, the difference is minor (see Table 2).
- The worst performance is obtained in the case of MobileNetV2 for both applied previews.
- The classifiers with a greater number of parameters indicate the higher performance (see Fig. 4, 5, and 8). Moreover, the results of the use of atomic preview is less sensitive to this feature.

Next, analyzing the coincidence of predicted classes with the highest probability, we get that

- The application of both previews provides a high percentage of coincidence of the most likelihood class.
- The use of Haar preview performs better, when very deep CNNs are applied (NASNetMobile and NASNetLarge). However, the difference is minor.
- The models with less layers produce better results when one uses the atomic preview. Wherein, the highest difference is indicated for the case of the MobileNetV2 classifier.
- For atomic preview, the impact of the model's characteristics is stronger than for the case of Haar preview.

Finally, comparing the models, we see that VGG19, which has the greatest number of parameters, demonstrates the best performance, when using a preview for classification of a source. And the MobileNetV2 network demonstrates the worst results.

V. Discussion

The performed comparison shows that a set of CNN-based image classifiers provides nearly the same results of the analysis of an image and its atomic preview, which is reconstructed using the blocks B_{00} of DAT coefficients, are close to each other. We remark that the efficiency of the considered models is not evaluated. In fact, we measure how much MobileNetV2, VGG16, VGG19, ResNet50, NASNetMobile, and NASNetLarge change their "opinion" if we replace the original image with a preview. The obtained results show that the difference is not major.

The conducted analysis uses a set of large scale digital photos. The transfer from a source to a preview can be treated as a special resizing technique. It is obvious that this procedure produces the loss of data. Nevertheless, the obtained results show that the most significant features are preserved. However, for the case of small size images, such a degradation might be great. Moreover, the same effect is expected if DAT's depth is increased. We suggest to use such a value of the hyperparameter m, which provides atomic preview of the size close to the input size of the model that is planned to be used.

In this research, neural networks of different architectures are explored. Generally, they demonstrate high robustness to the replacement of a source image with its preview constructed using DAT and Haar wavelet coefficients. The applied function systems have non-similar fundamental features, in particular, the order of smoothness, compactness, and approximation properties [17, 22]. For this reason, the same results could be obtained for other wavelet systems.

Further, the comparison of the predictions provided by the considered models is carried out in the unsupervised manner. Indeed, the actual image classes are not utilized, when computing numerical indicators. An advantage of this approach is that it does not need labeled data, which makes it useful in a wide range of cases [15]. However, a significant drawback of the applied technique is the lack of ability to assess whether classification performance has improved or not. Meanwhile, it follows that the number of parameters has a greater impact on the studied metrics than the depth of a network.

Finally, the obtained results shows that image representation by atomic function is ML/CV-oriented with respect to image classification by CNNs. Indeed, an atomic preview, which is reconstructed using a single block of DAT coefficients, ensures classification of the whole image, i.e. the features' compactness property is also guaranteed. Besides, DAC files requires less memory than both JPEG files and raw data, and, therefore, the data compression property is provided. Moreover, the computed value of PSNR indicates that visually lossless compression is ensured.

In Fig. 9, a general image classification pipeline, which utilizes atomic embeddings, is shown. It could be deployed completely on edge devices or autonomous systems. If computational capabilities are limited, then such light-weight CNNs as MobileNetV2 should be used. Besides, DAT coefficients, which represent atomic preview of an image, could be transferred via communication networks to remote data centers. This could be performed without significant increase in network load, since the size of compressed blocks B_{00} is drastically small.

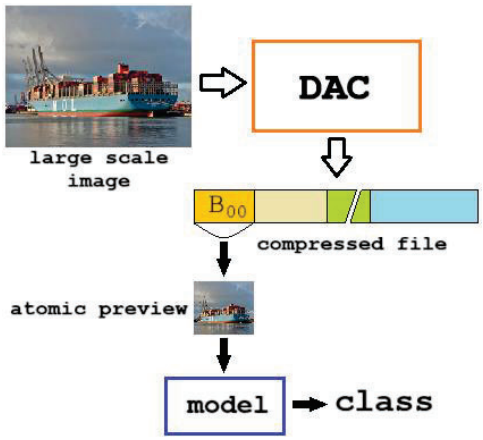

Fig. 9. Large scale image classification pipeline that utilizes atomic embeddings.

VI. Conclusions

This research has shown that image representation by atomic functions is ML/CV-oriented. The use of atomic image preview has been proposed, and its application to classifying source image has been investigated. The performed comparison has demonstrated that a set of state-of-the-art CNN-based classifiers produces nearly the same results, when analyzing either original image or its preview. The evaluated metrics, which measure this similarity in the unsupervised manner, have indicated that DAT is superior to the transform based on the Haar wavelet.

Thus, the use of the DAC algorithm provides data compression feature in combination with image format convenient for classification. The application of atomic image preview ensures the reduction of computations required for the preprocessing step. This makes the deployment of DAC on edge computing and autonomous systems promising.

herasymenko@ieee.org

***Abstract*—This paper presents the design and analysis of a high-voltage DC-DC converter based on the *LCL–T* resonant topology for capacitor charging in a combinational waveform generator compliant with IEC 61000-4-5. Traditional charging circuits often suffer from low efficiency, limited output current control, and difficulty in achieving soft-switching under varying load conditions. The proposed converter addresses these issues by ensuring zero-voltage switching, high efficiency, and output current stability regardless of the capacitor's charge level. The converter's behavior under the short-circuit and fully charged states is examined to confirm reliable operation in surge testing scenarios. Analytical design guidelines for the *LCL–T* resonant network are derived to maintain stable performance and reduce sensitivity to sudden load changes. Simulation results validate the converter's ability to deliver fast, dependable charging while protecting the power stage. Importantly, the inverter output current exceeds its nominal value by no more than 30% during transients, ensuring safe and predictable operation in pulsed power applications.**

I. Introduction

Modern electronic equipment should be safeguarded against surges. Lightning strikes, electrostatic discharges, motor power switching, and magnetic or inductive coupling can result in power surges (temporary spikes or transient overvoltage/overcurrent) [1]. Microsecond pulse generators are often used to evaluate the surge immunity of electronic equipment. These generators produce pulses by rapidly discharging a capacitor. Series-resonant converters have been used as power sources for capacitor charging applications in these generators [2]–[5]. However, changes in the output current of a series-resonant converter during operation, influenced by the capacitor's charge level, can cause hard switching modes of the converter transistors or excessive converter output current, especially during rapid capacitor discharge.

Several common capacitor charging techniques exist, such as resistive charging, high-frequency constant current charging, and resonant charging [6]–[10]. Resonant converters are particularly appealing for capacitor charging power supplies because of their zero-voltage and/or zero-current switching operation, high-frequency capability, high efficiency, compact size, and low electromagnetic interference [11]. The *LCL–T* resonant converter topology is especially well-suited for capacitor charging applications, as it provides inherent short-circuit protection at the output [11]–[13]. At the same time, more complex resonant networks are also being studied, since they are highly suitable for high-voltage applications [3].

For high-voltage capacitor charging, converters typically employ either a single-channel configuration, which consists of a high-voltage transformer with a complex rectifier composed of series-connected diodes, or a multi-channel setup, where multiple identical transformer-rectifier modules operate in parallel [2], [3], [5], [9], [14]–[16].

This paper presents a comprehensive design, analysis, and simulation of a high-voltage DC-DC converter based on the *LCL–T* resonant network, developed to ensure load-independent performance when powered by a constant DC source. The converter is intended for capacitor charging in microsecond pulse generators used in surge testing and other high-voltage pulsed power applications. The proposed topology enables zero-voltage switching and stable output current, regardless of the capacitor's charge level, addressing major drawbacks of traditional resonant and hard-switched converters. Analytical design conditions for the resonant circuit are derived to guarantee stable operation under both short-circuit and fully charged capacitor conditions.

II. Overview of IEC 61000-4-5 Surge Immunity Standard

A. Test Levels

The IEC 61000-4-5 standard defines the testing and measurement techniques for surge immunity assessment. It specifies multiple test levels corresponding to different environmental conditions. The table below summarizes the surge voltage levels and their associated meanings.

TABLE I
Test Levels

Level	Open-circuit test voltage $\pm 10\%$ [kV]
1	0.5
2	1.0
3	2.0
4	4.0
X[a]	Custom

[a]X can be any level above, below, or in between the other levels. This level can be specified in the product standard.

Different operating conditions classes require various types of combinational waveform generators (CWGs) during testing. The $10/700 - 5/320$ µs CWG is used to test ports designed for connecting symmetrical communication lines. In all other cases, including ports for power lines and short-distance signal connections, the $1.2/50 - 8/20$ µs CWG is used.

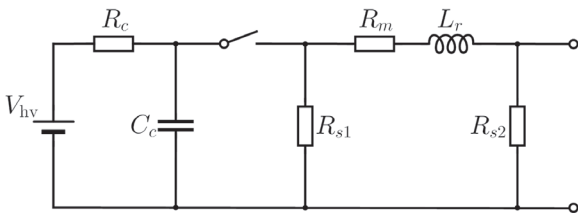

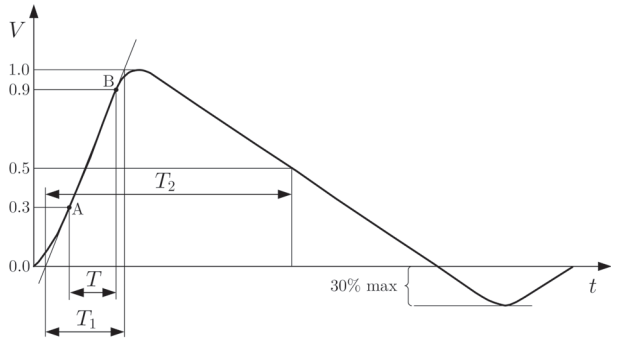

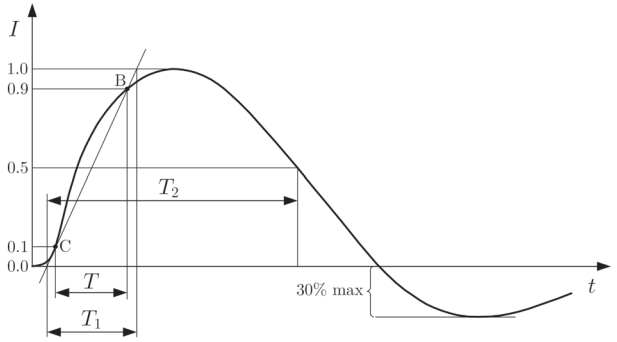

Fig. 1. Simplified combinational waveform generator.

(a)

(b)

Fig. 2. Waveform at the output of the CWG. (a) Open-circuit voltage waveform. (b) Short-circuit current waveform.

B. The Combinational Waveform Generator

The simplified CWG shown in the standard includes a power supply that charges the energy storage capacitor C_c through the resistor R_c (Fig. 1). The capacitor is charged from high-voltage source V_{hv}. When the switch closes, the C_c discharges through a pulse-shaping network consisting of the rise time shaping inductor L_r, two pulse duration shaping resistors R_{s1} and R_{s2}, and an impedance matching resistor R_m. The values of these components are chosen to generate the compliance, voltage and current waveforms under short-circuit and open-circuit conditions, as specified in IEC 61000-4-5.

C. 1.2/50–8/20 μs Combinational Waveform Generator

In existing IEC publications, voltage and current waveforms are defined based on IEC 60060-1 and IEC 60469. Both definitions apply to IEC 61000 and describe a single generator [17]. A standard surge waveform (Fig. 2) is characterized by its front time T_1 and time to half value T_2. Following IEC 60060-1, the open circuit voltage waveform of the $1.2/50$ μs shape has a front time of 1.2 μs ±30% and a time to half value of 50 μs ±20%. And the short-circuit current waveform $8/20$ μs shape has a front time of 8 μs ±20% and a time to half value of 20 μs ±20%.

The effective impedance of CWG, which is defined as the ratio of peak open-circuit output voltage to peak short-circuit current, has to be equal to 2 Ω±10%.

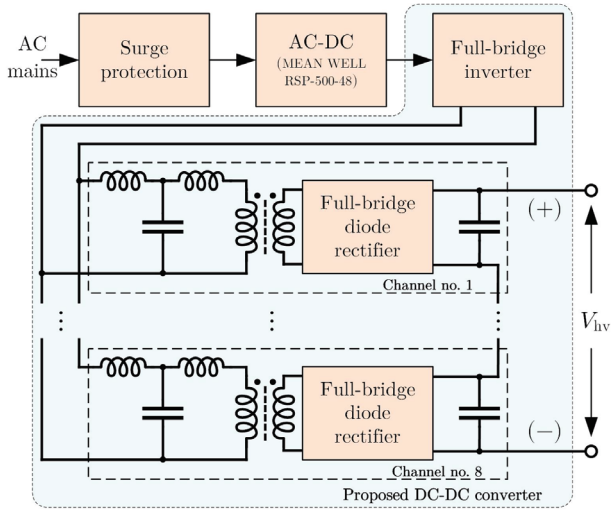

Fig. 3. Power supply system configuration of the 4 kV $1.2/50-8/20$ μs CWG.

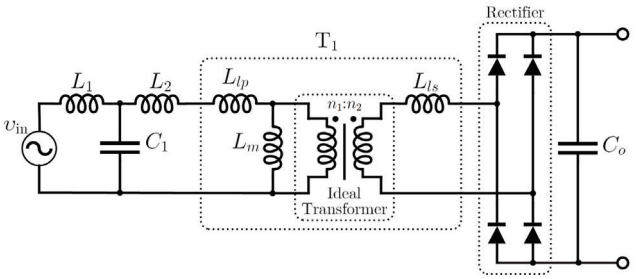

Fig. 4. Simplified circuit of the proposed DC-DC resonant converter.

In [18] and [19], step-by-step methods for determining the values of the parameters C_c, R_{s1}, R_{s2}, R_m, and L_r are shown. However, the values of these parameters can be significantly varied. And one of the criteria for their selection may be the availability of components with the desired nominal values.

III. Proposed DC-DC Converter

Fig. 3 shows the power supply system configuration of the 4 kV, $1.2/50-8/20$ μs CWG, which is based on the DC-DC resonant converter proposed in this paper. The power circuit of the DC-DC converter includes a full-bridge voltage-source inverter, eight channels of *LCL–T* resonant networks with full-bridge rectifiers. The inverter is powered by an AC-DC converter (MEAN WELL RSP-500-48). The power supply has a surge protection block to protect against pulses that may appear at its input as a result of its operation. If full isolation from the AC mains is required, the proposed DC-DC converter can be powered by a 48 V battery.

In the case of generating a 4 kV pulse, the peak output current of the CWG must reach 2 kA. Accordingly, the peak discharge current of capacitor C_c will be even higher. Therefore, the capacitor must be selected appropriately, particularly with a high pulse rise time rating (V/μs). Given that the required capacitance of this capacitor should be 6 μF or more, the proposed DC-DC converter includes eight channels, each containing a capacitor. The outputs of the channels are connected in series. For this purpose, a 60 μF, 900 VDC polypropylene capacitor from ELECTRONICON was selected for each channel. As a result, the total value of C_c is 7.5 μF.

The resistors R_{s1} and R_{s2} were each chosen to be 18.8 Ω and implemented using four series-connected 4.7 Ω resis-

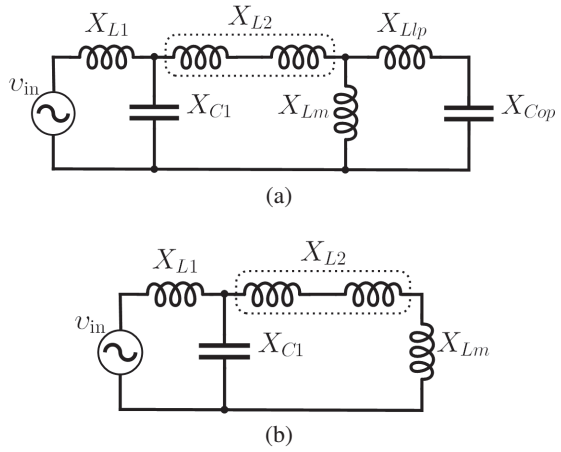

Fig. 5. Equivalent circuit of the proposed converter. (a) Under the short-circuit condition. (b) Under the charged condition.

tors (100 W aluminum-housed wire-wound resistors, model HS100, with a maximum rated voltage of 1900 VDC per element). The resistor R_m was chosen as 0.9 Ω and implemented using a series-parallel connection of 0.1 Ω power film resistors (MP9100-0.20-1%).

The inductor L_r was implemented as two series-connected air-core inductors, each with 15 turns, resulting in a total inductance of 9.5 μH.

A. Circuit Analysis

Fig. 4 shows a simplified circuit of the proposed DC-DC resonant converter. Since all eight channels with the *LCL–T* resonant networks operate in parallel under identical conditions, only a single channel is depicted to simplify the analysis. The *LCL–T* resonant network consists of two inductances L_1 and L_2, as well as the capacitor C_1. The matching transformer T_1 is represented by an equivalent circuit of a two-winding transformer, which includes the primary and secondary leakage inductances, L_{lp} and L_{ls}, as well as the magnetizing inductance L_m. The capacitance of the output capacitor C_o in every channel is 60 μF, as mentioned above.

For the circuit analysis of the proposed converter, it is expedient to consider two main cases: 1) short-circuit condition – when C_o is uncharged and the voltage across it is equal to zero, and 2) charged condition – when the capacitor C_o is charged to the desired voltage level. The first condition corresponds to the initial operation of the converter, as well as the moment when a pulse is generated at the output of the CWG during operation. The second condition corresponds to the state when the voltage across C_o has reached its maximum value, resulting in either no current or a very small current flowing through C_o.

1) Short-circuit condition: Fig. 5 (a) shows the equivalent circuit of the proposed converter under the short-circuit condition, reflecting the secondary parameters to the primary side of T_1.

The electrical impedance Z of the equivalent circuit can be described as follows:

$$Z = X_{L1} + Z_1 \parallel X_{C1} \tag{1}$$

where X_{L1} and X_{C1} are the reactance of L_1 and C_1, respectively, and Z_1 is the impedance, given by

$$Z_1 = X_{L2} + (X_{Cop} + X_{Llp}) \parallel X_{Lm} \tag{2}$$

where X_{L2} is the reactance of sum L_2 and L_{lp}, X_{Lm} is the reactance of L_m, X_{Llp} is the reactance of L_{lp}, and X_{Cop} is the reactance of the capacitor C_{op}, whose capacitance corresponds to that of C_o reflected to the primary side of T_1.

2) Charged condition: In the charged condition, the current flowing through C_o is very small, and the converter's output impedance can be considered very high. The equivalent circuit of the proposed converter for this case is shown in Fig. 5(b). In this case, Z is given by

$$Z = X_{L1} + Z_2 \parallel X_{C1} \tag{3}$$

where Z_2 is the impedance, given by

$$Z_2 = X_{L2} + X_{Lm}. \tag{4}$$

3) Resonant network design: One of the key criteria for selecting parameters of the resonant network is the desired switching frequency f_O of the converter. At this frequency, the impedances Z_1 and Z_2 should be relatively close to each other, so that a sharp change in the voltage across the capacitor C_o, resulting from its discharge, does not significantly affect the inverter's output current. Therefore, the following condition can be used as a design guideline for choosing the resonant network parameters:

$$Z_1 \gtrsim 0.5 Z_2. \tag{5}$$

Considering condition (5), and based on (2) and (3), it can be determined that the reactance X_{L2} should be at least two times greater than X_{Lm}. Assuming that L_{lp} is significantly smaller than L_m, the following condition should be satisfied when selecting L_2:

$$L_2 \gtrsim L_m. \tag{6}$$

To ensure that the proposed converter operates as a current source supply, regardless of the voltage across C_o, the following condition must be satisfied:

$$X_{C1} \ll Z_1. \tag{7}$$

However, if Z_1 is much greater than X_{C1}, the charging process may become too slow, or the amplitude of the inverter's output current may become excessively high. As a compromise, it is reasonable that the reactance X_{C1} at f_O should be approximately 20% of Z_1. Under this assumption, the value of C_1 can be estimated as:

$$C_1 \approx \frac{1.25}{(\pi f_O)^2 L_2}. \tag{8}$$

The value of L_1 should be selected so that the resonant frequency f_r of the *LCL–T* resonant network is slightly lower than f_O.

It should also be noted that Z at f_O, resulting from the selected component values of the *LCL–T* resonant network, should correspond to the desired maximum output current level of the converter's inverter.

B. Characteristic Diagrams of the Proposed Converter and Frequency-Sweep Analysis

Table II presents the selected component values of the *LCL–T* resonant network for the proposed converter.

As a result of manufacturing, the magnetizing inductance L_m of the matching transformer may be too high. In this case, it is advisable to introduce an air gap in the core to reduce this

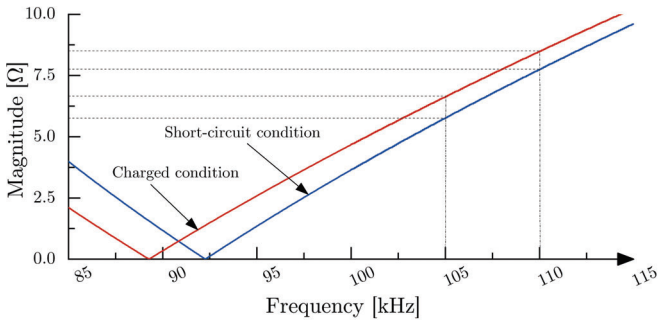

Fig. 6. Frequency response of the impedance magnitude for the selected *LCL–T* resonant network components.

TABLE II
SELECTED COMPONENT VALUES

Item	Value
L_1	33 µH
C_1	0.11 µF
L_2	150 µH
L_m	82 µH
C_{op}	82 µF

value. Alternatively, an additional inductor can be connected in parallel with the primary winding of the transformer. In this case, the effective magnetizing inductance L_m can be considered as the equivalent of the parallel combination of the transformer's inherent magnetizing inductance and the added inductance.

Fig. 6 shows the frequency response of the impedance magnitude $|Z|$ under short-circuit and charged conditions, based on the selected component values of the *LCL–T* resonant network. It can be observed that at the operating frequency range of 105 kHz to 110 kHz, the impedance magnitude varies by approximately 14%. In the case of frequency-sweep operation, where f_O decreases from 105 kHz to 103 kH during the charging process to maintain a more constant charging current for C_o, the system impedance changes more significantly when transitioning from the charged condition to the short-circuit one. Overall, the impedance variation during operations does not exceed 16% even under frequency-sweep operation, which ensures that the proposed converter can effectively operate as a current-source supply.

IV. SIMULATION RESULTS

To verify the theoretical analysis, the proposed DC-DC resonant converter was implemented in the MATLAB/Simulink environment, and its operation was simulated under two conditions: short-circuit and open-circuit (Fig. 7).

To evaluate the system's behavior under the short-circuit condition, waveforms of the inverter output current i_O, high-voltage output V_{hv}, and current i_{out} through the inductor L_r are shown in Fig. 8. The detailed view of the i_{out} waveform demonstrates that the shape of the current pulse fully meets the requirements of IEC 60060-1. At the same time, the waveform of i_O shows that, from the moment the short-circuit condition occurs, its amplitude level exceeds the pre-short-circuit condition amplitude level by approximately 30%. This overshoot is higher than theoretically expected and can be attributed to the appearance of a transient oscillatory process. Over time, the oscillations decay, and the amplitude of i_O approaches the theoretically expected value. This effect should be taken into account during converter design.

Fig. 9 presents current waveforms through the elements of the *LCL–T* resonant network. These waveforms show that although the current i_{L2} through L_2 increases by slightly

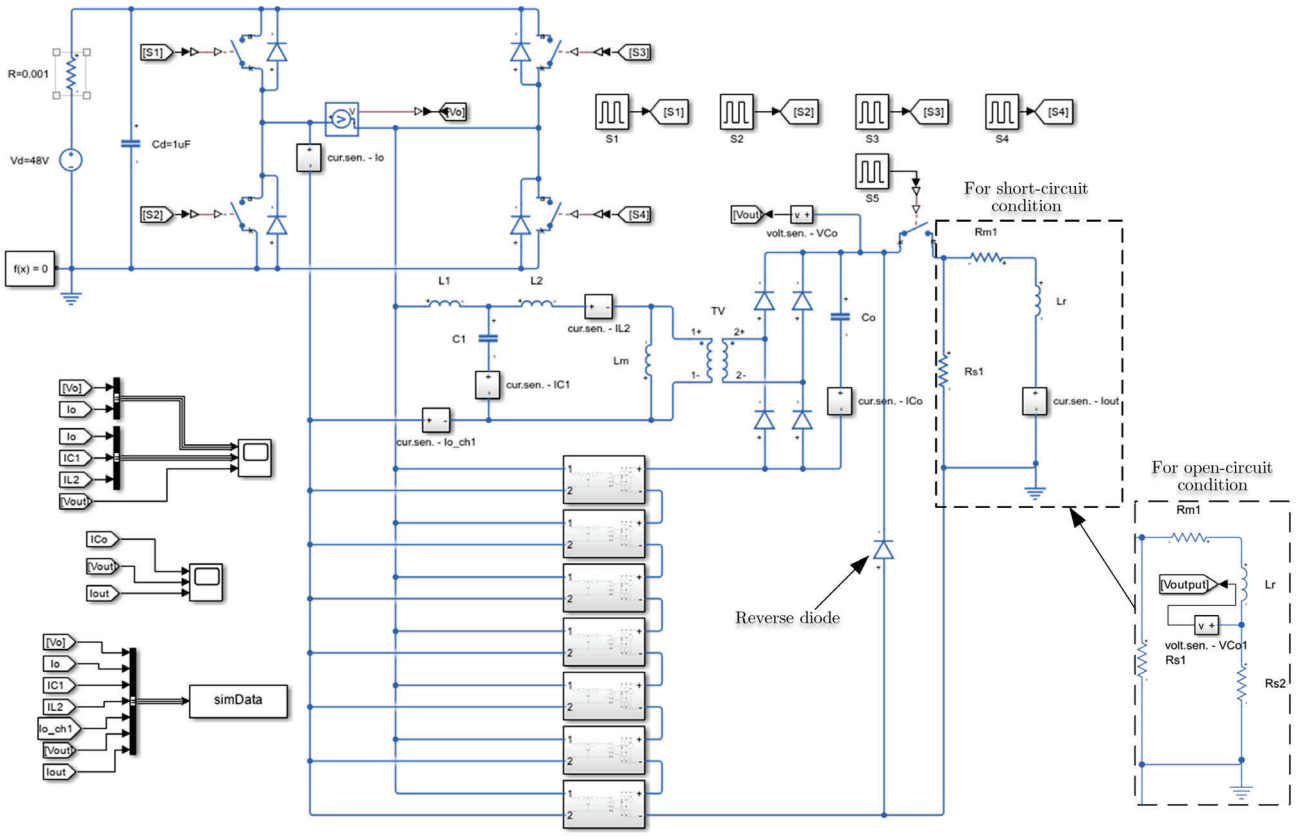

Fig. 7. Converter simulation model in the MATLAB/Simulink environment.

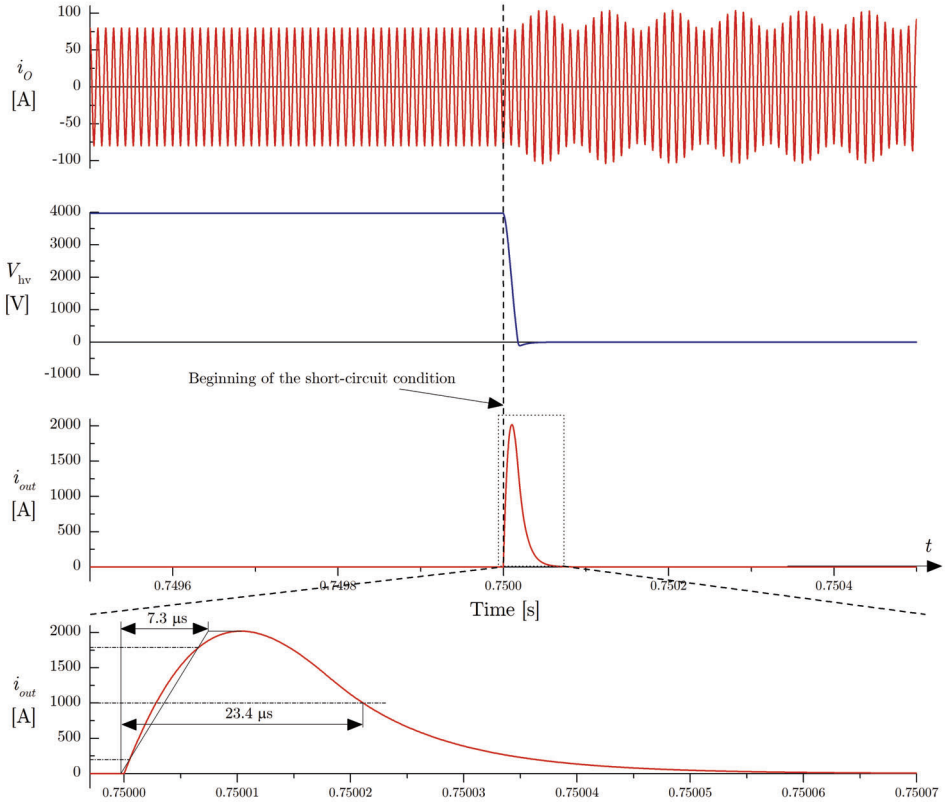

Fig. 8. Waveforms of the inverter output current, high-voltage output and current through the inductor L_r under the short-circuit condition.

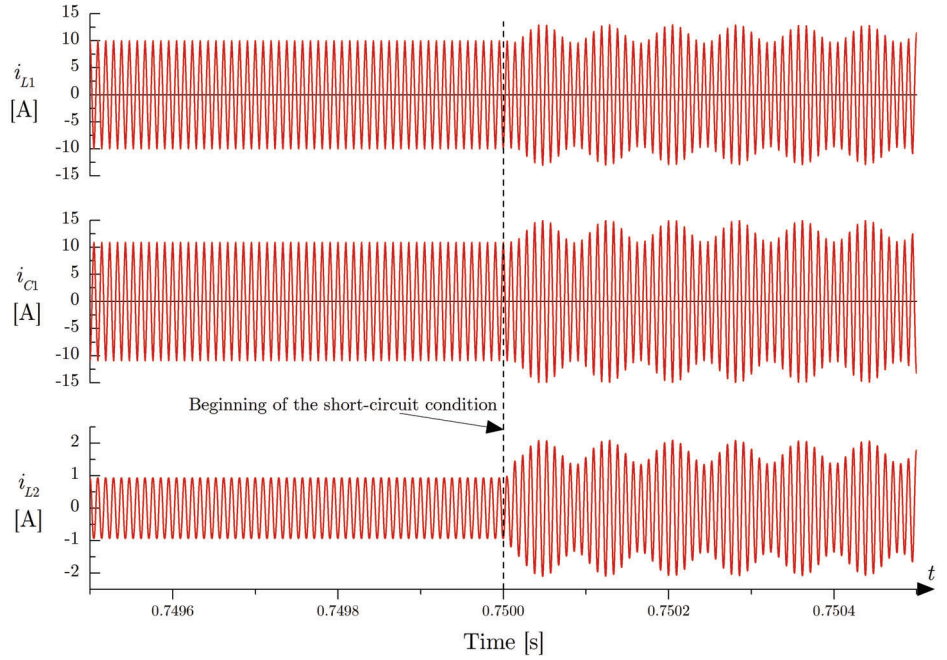

Fig. 9. Current waveforms through elements of the *LCL–T* resonant network in the case of the open-circuit condition.

more than a factor of two after the short-circuit condition, the amplitude of the current i_{L1} through L_1 increases by only about 30%.

Additional insights are provided in Fig. 10, which shows the high-voltage waveform V_{hv} in the absence of the reverse diode shown in Fig. 7. The diagram illustrates that V_{hv} can reach –680 V, caused by the current i_{out} flowing through 16 series-connected diodes of the converter channels. Based on this, the inclusion of the reverse diode is recommended to prevent excessive reverse voltage.

Fig. 11 shows the waveform of the output voltage υ_{output} at the output of the CWG under the open-circuit condition. The voltage υ_{output} corresponds to the voltage across R_{s2}. As seen from the waveform, the pulse shape fully complies with the requirements of IEC 60060-1. It should be noted that the obtained peak value of υ_{output} reaches only 3670 V with a transformer turns ratio of $n_1 : n_2 = 1 : 13$. To achieve 4 kV, this ratio should be increased to $1 : 14$.

Conclusion

This paper presented a high-voltage DC-DC converter based on the *LCL–T* resonant topology for capacitor charg-

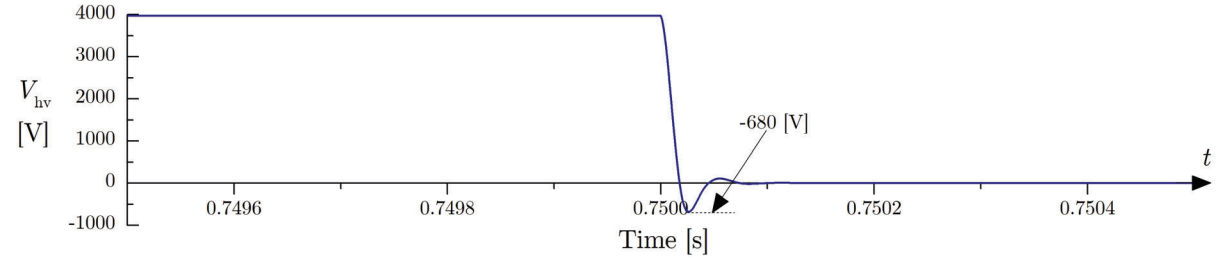

Fig. 10. High-voltage waveform in the case of the absence of the reverse diode.

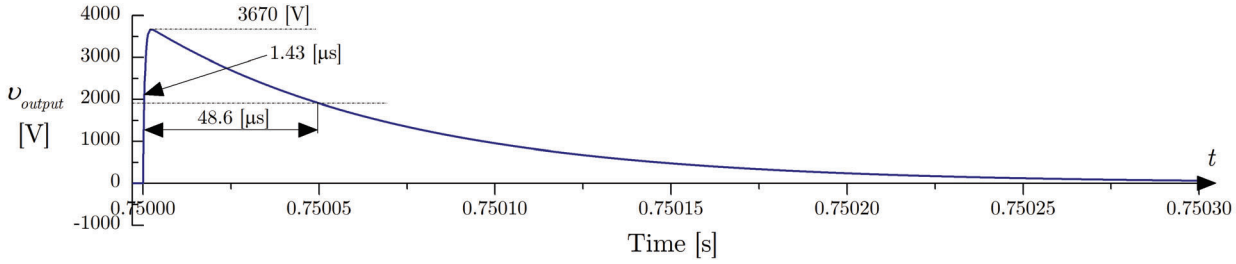

Fig. 11. Voltage waveform at the output of the CWG under the open-circuit condition.

ing in a combinational waveform generator (CWG) compliant with IEC 61000-4-5. The solution ensures zero-voltage switching, high efficiency, and output current stability regardless of the capacitor's charge. The converter's behavior under the short-circuit and fully charged conditions was analyzed, and design criteria for the resonant network were derived to ensure stable operation under varying load impedances. Results confirm that the *LCL–T* topology offers inherent protection and reliable performance for surge testing equipment, with the inverter output current exceeding the nominal value by no more than 30% during transients.

***Abstract* — The paper considers an improved design of a fuse for the protection of the medium voltage instrument transformer. The problem of switching off by fuses of small overload currents and the low efficiency of their use for protecting voltage transformers are analyzed. Thermal images of the temperature distribution of the studied fuse are presented and the time and temperature at which its operation occurs are established. The time-current characteristics of the developed fuse are obtained and a comparison is made with samples from well-known manufacturers. The competitiveness of the new fuse design is established and directions and prospects for further development are proposed.**

Keywords* — *medium voltage instrument transformer, fuse, fuse-link, voltage transformer protection, instrument transformer primary winding current

I. INTRODUCTION

As shown in [1–4], in the medium voltage distribution network of 6–35 kV with an isolated neutral, the problem of protecting instrument voltage transformers (VTs) is relevant, which is associated with insufficiently effective level of their protection using fuses [5, 6]. A feature of the operation of VTs is that they operate in a mode close to no-load. The primary winding of the VT, in the circuit of which the fuse is installed, has a very high resistance and, accordingly, the current flowing through the winding is quite small and in the nominal mode is determined by no-load losses, which is approximately 10–20 mA. At the same time, the current Standard [7], and, accordingly, domestic manufacturers of fuses for VT protection [8, 9], do not standardize the values of the rated fuse current I_n, the maximum rated breaking current I_1 and the minimum rated breaking current I_3. At currents less than current I_3, the fuse-links burns out, but the fuse does not interrupt the current (the electric arc does not extinguish) [10, p. 270]. Therefore, the switching off by fuses of namely small overload currents is a problem. And, conversely, in the case of emergency situations accompanied by a significant increase in the flowing current, fuses effectively protect VTs by melting the fuse-links.

The most frequent dangerous situations in a medium-voltage network with an isolated neutral include overvoltages and resonance (ferroresonance) phenomena [11–19]. Their causes are various factors: ground fault; operation of a fuse in one of the phases; lightning surges, etc. [20–23]. But the most common cause of overvoltages is single-phase ground faults due to an alternating arc, as a result of which resonance phenomena and dangerous overvoltages can occur. In this case, the current in the primary winding of the VT can increase several dozen times, which can lead to its destruction [14, 24]. This is especially true for VTs with cast epoxy insulation, which is very sensitive to temperature increase due to current increase. This problem is not so acute in the case of operation of VTs with oil insulation, which, as is known, also performs the function of additional cooling. But, taking into account the disadvantages of oil insulation (large dimensions of the VT, fire hazard, need for periodic maintenance, etc. [25]), the vast majority of manufacturers and operators switch to using VTs with cast epoxy insulation.

From the experience of operating VTs, there are common cases when their protection is provided by such fuses in which the rated current of the fuse-link is significantly higher than the maximum permissible continuous current of the primary winding of the VT [6]. Thus, the designs of fuses require further improvement in order to increase the efficiency of VT protection.

As shown by an analytical review of known solutions in the field of protection of medium voltage VTs using fuses [5, 6, 8, 9, 26–28], today the efficiency of VT protection is not high enough, as evidenced by the increase in the number of their damages. Therefore, research in this area is relevant.

The goal of the paper is to improve the design of a fuse for protection of medium voltage VTs and conduct preliminary experimental studies of the development.

II. EXPERIMENTAL RESEARCH

A prototype of a fuse-link placed on an experimental stand, manufactured at the Department of Electrical Apparatus of National Technical University «Kharkiv Polytechnic Institute» in cooperation with the manufacturer of electrical equipment «ABM AMPER» LLC, is shown in Fig. 1.

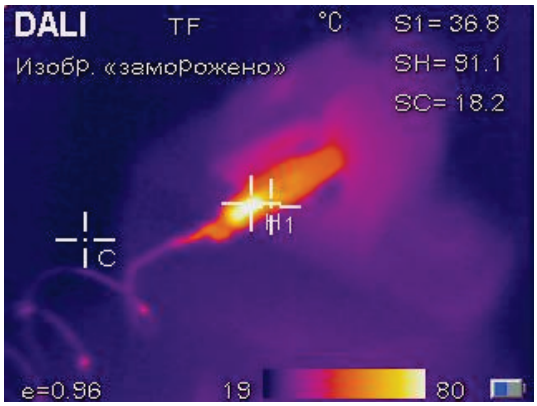

Fig. 1. Stand for experimental research of a fuse

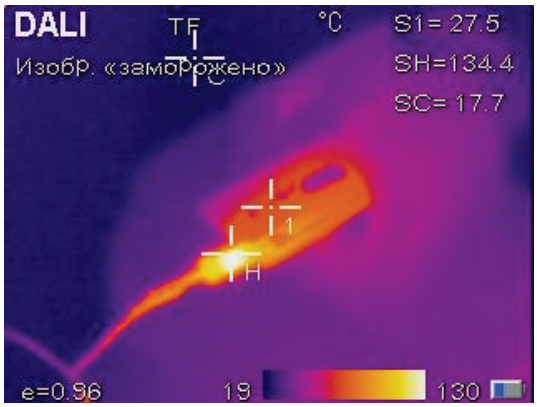
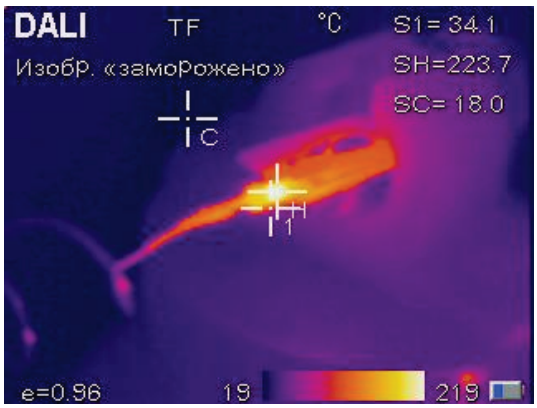


The basis of the manufactured experimental design of the fuse is taken from the developments described in detail in [6, 26], but with new solutions.

A metal bracket is installed on the insulating base of the replaceable fuse-link, to which, in turn, the resistor terminal is attached on one side, and to the other one – the fuse spring in the cocked position. When current flows, the fuse-link heats up, and at a certain value of it, the spring is triggered, switching off the circuit. By using materials with a lower melting temperature in the developed experimental design of the fuse compared to the basic version, it was possible to reduce the fuse operating time precisely in the range of small overload currents. A more detailed description of the design of the fuse and its operating principle is not disclosed, because it constitutes a commercial secret and is the subject of patenting.

In order to determine the temperature of the fuse-link at which the fuse operates, a series of experiments were conducted with thermal imaging of the temperature distribution pattern using a thermal imager. The results of the studies are shown in Fig. 2. Reliable operation of the fuse occurred at current of about 120 mA at temperature of about 180 °C (the ambient temperature during the studies was 18 °C).



a) I = 80 mA, T = 91 °C

b) I = 100 mA, T = 134 °C

c) I = 120 mA, T = 177 °C

d) I = 140 mA, T = 223 °C

Fig. 2. Results of measuring the temperature of the fuse-link

The next stage of experimental research was to obtain the time-current characteristics for the developed prototype fuse and compare them with the characteristics of common fuses from other manufacturers – ESKA [27] and SIBA [28]. The rated current of all fuses participating in the study was I_n = 80 mA.

A comparison of the time-current dependencies obtained from the research results of the developed prototype fuse with the characteristics of ESKA and SIBA fuses is shown in Fig. 3 and given in Table 1. The data on the average operating time t_{av} in Table 1 were calculated as the average of the results of five experiments conducted.

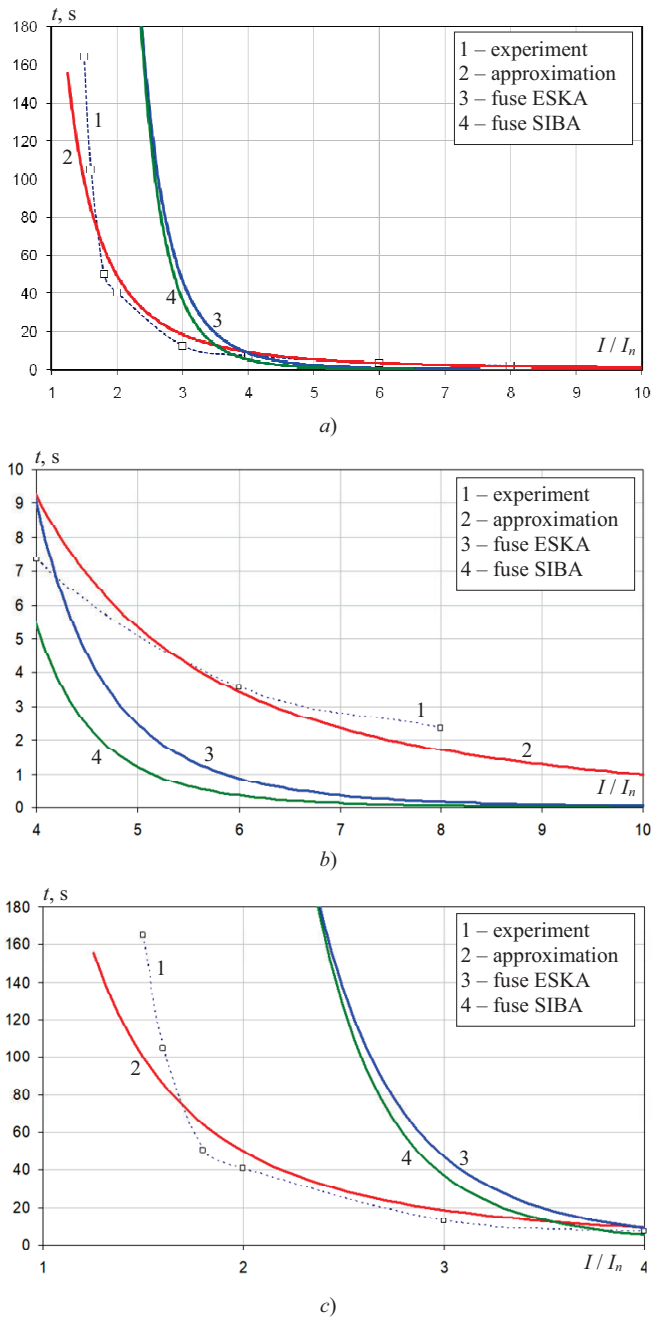


Fig. 3. Comparison of time-current characteristics of the developed fuse with ESKA and SIBA fuses:
a) in the entire range of current multiplicity (I / I_n) – from 1.5 to 10;
b) in the range of large current multiplicity (I / I_n) – from 4 to 10;
c) in the range of small current multiplicity (I / I_n) – from 1.5 to 4

It has been established that the experimental results of the measurement of the fuse operating time can be approximated with sufficient accuracy by the least squares method. The formula for approximating the obtained results of the measurement of the fuse operating time t depending on the current i has the following form:

$$t = 265.8 / i^{2.4} . \quad (1)$$

TABLE I. RESULTS OF EXPERIMENTAL STUDIES OF THE TIME-CURRENT CHARACTERISTICS OF THE DEVELOPED FUSE

I, mA	80	100	120	128	144	160	240	320	480	640
I / I_n	1	1.25	1.5	1.6	1.8	2	3	4	6	8
t_{av}, s	–	–	164.6	105.0	50.4	40.7	12.5	7.3	3.5	2.4

III. ANALYSIS OF THE RESULTS OBTAINED

Analysis of the results of experimental studies shows that the nature of the time-current characteristic for the developed sample in comparison with the ESKA and SIBA fuses is quite close (Fig. 3,*a*). At the same time, when comparing, it is worth noting a certain zonality of the time-current characteristic depending on the current multiplicity. For example, in the range of large emergency overcurrents I / I_n = 4 – 10, the developed fuse is inferior in operating time to foreign manufacturers (Fig. 3,*b*), but with increase in the emergency overcurrent, a decrease in the difference in operating time can be observed. As noted above, fuses cope more effectively with large emergency currents, and the problem is namely the switching off small overload currents. That is why it is necessary to pay attention to the nature of the time-current characteristic of the developed sample namely in the range of small overload currents I / I_n = 1.5 – 4 (Fig. 3,*c*). As we can see, in this range the developed fuse better protects the VT, significantly outperforming foreign manufacturers, and, therefore, is competitive and promising.

In addition, it should be noted that in the range of large emergency overcurrents I / I_n = 4 – 10 (at small rated current I_n = 80 mA these are currents of 320 – 800 mA) the increased operating time of the developed fuse may not be a critical drawback. In case if the thermal resistance of the VT is sufficient (for example, these may be the same VTs with oil insulation), then thermal inertia will protect the fuse from operation during probable short-term current surges, which are common in medium voltage networks.

CONCLUSIONS

Analysis of the current state and experience of operation of electrical equipment in the medium voltage electrical network of 6–35 kV revealed that today there is a pressing problem associated with the low level of efficiency of VT protection by fuses. It was established that there are frequent cases when VT protection is provided by fuses, in which the rated current is significantly higher than the maximum permissible continuous current of the primary winding of the VT.

An improved design of a fuse for protecting medium voltage VTs is considered in the paper and preliminary experimental studies have been conducted.

The obtained research results in the form of time-current characteristics showed the competitiveness of the new design, especially in the range of small overload currents, which is especially important for VT protection.

Since in Ukraine the needs for fuses for VT protection are mainly met by supplies from abroad, a promising direction for further development in this direction is the creation of a domestic competitive design of a fuse and its implementation in production.

Also, as a prospect for further development, it is planned to create a small batch of industrial samples of fuses for VT protection on the basis of «ABM AMPER» LLC in order to conduct in-depth experimental research to identify shortcomings and find the optimal design.

***Abstract*—This study presents a new approach to synthesizing the CdO/por-CdS/CdS heterostructure to improve solar energy conversion. We achieved a heterostructure with unique morphological and crystalline features by utilizing an anodic and cathodic processing method in an acidic solution followed by oxygen annealing. Scanning Electron Microscopy (SEM) revealed a complex surface topology combining elliptical and circular pores, providing a substantial active surface area. Energy-dispersive X-ray (EDX) analysis confirmed the elemental composition, indicating the presence of CdS and CdO or CdSO phases. Raman spectroscopy and X-ray Diffraction (XRD) allowed us to discern the crystallinity of CdS and the potential amorphous nature of the CdO layer. The intricate design of the heterostructure facilitates efficient light absorption, charge separation, and electron transport, which is critical for solar energy devices. This research contributes to developing photovoltaics and photocatalysis, presenting a heterostructure that leverages the synergistic properties of CdS and CdO for improved solar energy conversion.**

Keywords— CdO, CdS Heterostructures, Electrochemical Synthesis, Cadmium Oxide, Raman Spectroscopy, Semiconductor

I. INTRODUCTION

Recent advancements in nanomaterial studies have illuminated nanomaterials' unique luminescent and vibrational properties, contributing to the continuous development of new applications in renewable energy sectors [1-3]. Furthermore, the impact of defects on the structural and electronic properties of nanostructures emphasizes the importance of controlled synthesis and characterization for utilizing the full potential of nanomaterials in various technological applications [4]. Cadmium sulfide (CdS), with its narrow band gap and sensitivity to visible light, stands out as a quintessential photocatalyst capable of harnessing solar light across a broad wavelength range of 200–600 nm [5, 6]. CdS has attracted significant attention due to its excellent photocatalytic characteristics and high photoelectric conversion efficiency, making it a subject of intensive research [7, 8]. In photocatalysis, CdS demonstrates promising research prospects in water restoration, photocatalytic hydrogen production, and CO_2 reduction [9]. Similarly, CdS shows considerable application potential in photoelectrochemistry in photoelectrochemical (PEC) water splitting [10]. Nevertheless, the broader application of CdS is impeded by its susceptibility to photo corrosion and the rapid recombination of photogenerated electron-hole pairs [11, 12]. It has been proven that modifications of CdS, including morphological engineering, elemental doping, and heterojunction construction, effectively enhance its photocatalytic and PEC properties [13, 14]. The emergence of nanomaterial science has marked a transformative stage in advancing scientific efforts, primarily due to nanostructures' unique capabilities for a wide array of technological and applied objectives [15]. Semiconductor and dielectric nanomaterials, in particular, are pivotal to progress in photovoltaics and optoelectronics [16, 17].

Heterostructural materials have sparked intense scientific interest due to their exceptional properties and immense technological potential [18]. A variety of cadmium-based heterostructures have been studied [19, 20]. However, pursuing optimal heterostructure quality often encounters challenges such as lattice mismatch and the introduction of stress at the material interfaces [21]. One strategy to mitigate these issues involves using an intermediate buffer layer.

Porous layers serving as compliant substrates are increasingly recognized as a promising strategy to alleviate stress and reconcile lattice discrepancies [22]. Numerous methodologies exist for creating such porous architectures. While modern methods like ion-track templating merit attention [23], traditional methods such as electrochemical etching remain relevant due to their simplicity and capability for large-scale synthesis [24].

In this context, our research presents a new methodology for synthesizing the CdO/por-CdS/CdS heterostructure through the electrochemical treatment of the CdS surface. We comprehensively analyze the heterostructure's morphological, compositional, and structural attributes, allowing an in-depth understanding of its intrinsic properties and potential for solar energy conversion applications.

II. Materials and Methods

The heterostructure was grown on the surface of wurtzite hexagonal CdS using a combined method that included anodic and cathodic processing in an acidic solution followed by oxygen annealing. The mechanism of action involves anodic treatment in the electrolyte, after which the solution is saturated with acid, changing the position of the anode and cathode for cathodic processing. Subsequently, the samples undergo annealing in an oxygen atmosphere for saturation.

The samples were electrochemically treated in a specialized three-electrode cell consisting of two working electrodes and an additional comparison electrode (chloro-argentum EVL1M3). A potentiostat was used for accurate current measurements, which ensured a fixed distance of 1.5 cm between the sample and the platinum electrode. The cell was equipped with additional functional modules, including an air blower and mixer, which facilitated uniform solution mixing during the process.

A. Anodic Etching

The initial stage involved forming a porous layer on the surface of CdS through electrochemical etching. This process was conducted in a 5% aqueous HCl solution at room temperature under potentiostatic conditions, maintaining a voltage of 5V. Group A2B6 semiconductors, such as CdS, are less efficiently etched in acidic solutions than group A3B5 semiconductors, so uniform pore nucleation was facilitated by in situ illumination. This was achieved by focusing UV radiation from a 200W Xe lamp onto the CdS surface. The etching lasted 3 min, during which bubble emission was noted at both the anode and cathode, indicating oxygen and hydrogen release from the electrolyte. Active mixing of the solution was employed to mitigate this effect and ensure effective etching. The electrolyte was at room temperature, and the experiment was conducted under natural lighting conditions. A pronounced increase in current density was observed, signifying the activity of electrochemical processes at the electrolyte-semiconductor interface. Additionally, the change of color of the electrolyte solution to yellow indicates the presence of cadmium ions released from the crystal surface.

B. Cathodic Deposition

The next stage focused on depositing the electrochemical reaction products onto the semiconductor, mainly forming CdO. To implement this step, the semiconductor wafer and platinum were swapped to facilitate cathodic deposition, reversing anodic etching. This process was carried out in the same electrolyte solution under a potential of 5V for 3 min. During this phase, the reduction process of ions at the cathode led to material deposition.

C. Oxygen Annealing

The final step in the manufacturing process was oxygen annealing, which played a crucial role in enhancing the quality and efficiency of the applied layers. Annealing was conducted in a JetFirst diffusion furnace, which was chosen for its precision in temperature control and uniform heating. The samples were annealed at a temperature of 150°C for 20 min. After annealing, the samples were thoroughly dried and stored outdoors for three months, stabilizing the environment naturally.

D. Characterization

Scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDX) analyzed surface morphology and composition.

Structural characteristics were investigated through Raman spectroscopy, utilizing a Solver Spectrum spectrometer from NT-MDT, operated in a 180-degree reflection mode. The primary excitation source in this process was a laser, characterized by a wavelength of 473 nm. The size of the laser beam when it made contact with the sample was approximately 2 micrometers in diameter.

III. Results

A. SEM Analysis

Fig. 1 presents the surface morphology of CdS after the electrochemical etching process. SEM analysis reveals that etching led to significant etching pits on the CdS surface, demonstrating two predominant types of visible pores.

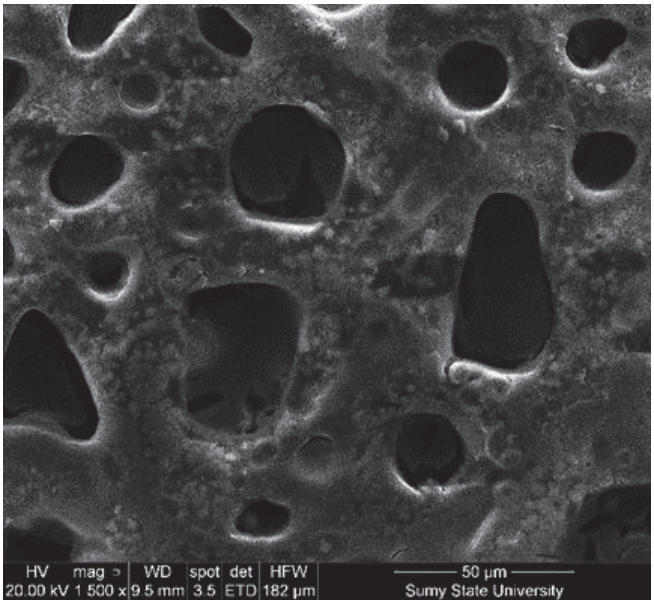

Fig. 1. SEM image of the porous CdS surface.

The first type of pores predominantly exhibits an elliptical shape, with the significant axis measuring approximately 50 µm. These large elliptical etching pits are likely the result of anisotropic etching, where different crystallographic orientations exhibit variable etching rates. Such anisotropy in the etching process can be attributed to the inherent crystalline structure of the CdS material, which has distinct planes of weakness that are more susceptible to the etching solution.

In contrast, the second type of pores is more uniform in shape, displaying a circular cross-section with a diameter of about 20 µm. These circular pores could form from isotropic etching, occurring at the same rate in all directions, leading to more uniform shapes. These pores are relatively smaller than the elliptical ones and suggest a different etching dynamic, possibly influenced by localized variations in current density, impurities, or defects acting as etching sites.

Furthermore, the surface is dotted with numerous tiny pores with diameters not exceeding 1 µm. The distribution of these minute pores suggests a delicate etching process,

possibly due to the prolonged action of the acidic solution or as a culmination of the electrochemical etching towards the end of the process when the more giant pits had already formed.

The diversity in pore sizes and shapes could benefit solar energy conversion applications. It may lead to a larger active surface area and more interfaces, which is advantageous for photon absorption and subsequent charge carrier generation. Moreover, the variation in pore morphology could facilitate the hierarchical assembly of nanostructures within the pores, enhancing light trapping and increasing charge transport efficiency.

Overall, the SEM image illustrates a complex three-dimensional surface topology indicative of meticulous control exerted during the electrochemical etching. This controlled porosity is critical for the subsequent deposition of CdO and the expected enhancement in the optoelectronic properties of the heterostructure.

Fig. 2 presents the morphology of the grown CdO/por-CdS/CdS heterostructure.

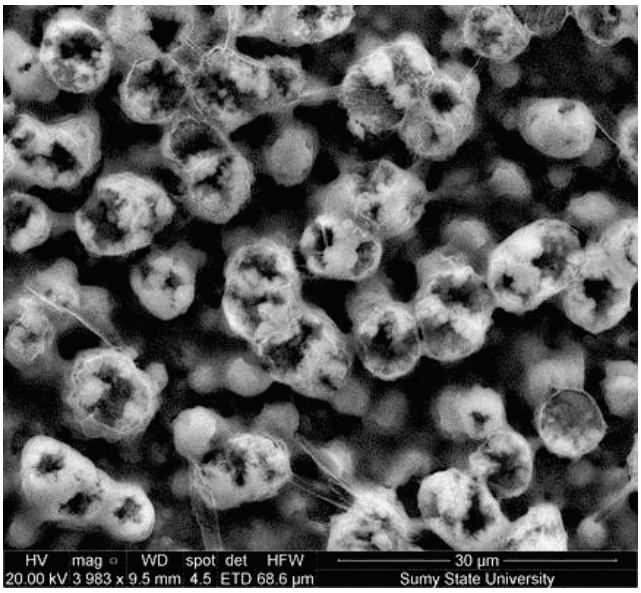

Fig. 2. SEM image of the CdO/por-CdS/CdS heterostructure.

The SEM image allows us to observe white regions, which are massive rounded formations with a loose, porous internal structure. The presence of voids within these globules indicates that material deposition resulted in the formation of not a continuous film but discrete porous clusters. These white globules signify the presence of cadmium oxide (CdO) or potentially a more complex structure, such as cadmium sulfite (CdSO), deposited on top of the initial porous cadmium sulfide (CdS) layer. The dark areas in the image represent voids between the spherical formations. This contrast is due to the differential scattering of electrons, where the electron beam is absorbed or deflected more by denser globules than voids. The mechanism leading to forming these globular structures with internal voids can be attributed to the kinetics of the electrochemical deposition process. During cathodic deposition, cadmium ions are reduced on the cathode surface, forming cadmium oxide. The presence of acid in the solution might lead to the formation of CdSO due to the reaction of cadmium ions with sulfur forms. The loose internal structure of the globules indicates that during the growth process, conditions favored rapid outward expansion of the material rather than uniform layer-by-layer growth. This might be related to localized supersaturation conditions where rapid deposition outpaces the ion migration required for a more compact crystal lattice formation. Furthermore, the stage of oxygen annealing could have influenced the morphology and internal structure of the globules. The annealing process might cause diffusion of atoms within the globules, potentially creating or enlarging internal voids, a phenomenon observed in some annealed metal-oxide systems. From a kinetic perspective, the development of this morphology suggests that a complex interplay of reaction rate and diffusion governs the process. The local microscale environment, including pH variations and local electric fields, can significantly influence the deposition process, leading to the heterogeneous morphology observed in the SEM image.

B. EDX Analysis

EDX spectroscopy was employed to analyze the elemental composition of the synthesized CdO/por-CdS/CdS heterostructure (Fig. 3, Table 1).

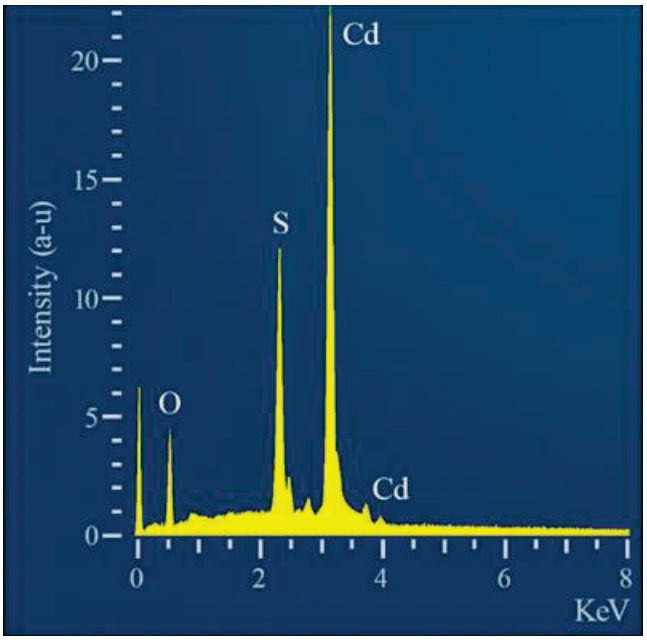

Fig. 3. EDX spectrum of the CdO/por-CdS/CdS heterostructure.

TABLE I. ELEMENTAL COMPOSITION OF THE CDO/POR-CDS/CDS HETEROSTRUCTURE

Element	Atom, %
Cd	31,13
S	31,79
O	37,08

The EDX data reveal a significant presence of oxygen, accounting for 37.08% of the atomic composition. This high percentage of oxygen aligns with cadmium oxide (CdO) formation in the heterostructure, corroborating the SEM observations of white globular masses indicative of CdO or possibly a complex cadmium compound.

The nearly equivalent atomic percentages of cadmium (Cd) and sulfur (S), both approximately 31%, suggest that the CdS layer remains a notable component of the

heterostructure. This balance between cadmium and sulfur atoms is consistent with the stoichiometry of cadmium sulfide (CdS), reflecting the successful preservation of the CdS layer during the synthesis process.

The presence of sulfur in the overall composition also indicates the possibility of cadmium sulfite (CdSO) formation, as the SEM analysis suggested the potential presence of complex structures within the globules. The reaction between cadmium ions and sulfur species in the acidic solution during the cathodic deposition stage might lead to the formation of such a compound.

The EDX analysis thus indicates that the heterostructure comprises a significant amount of oxygen, surpassing the atomic percentages of cadmium and sulfur. This observation might indicate forming a cadmium oxide-rich layer or cadmium compounds with higher oxygen content.

C. Raman Analysis

The synthesized CdO/por-CdS/CdS heterostructure's Raman spectrum displays a series of peaks that shed light on the vibrational modes of the constituent materials (Fig. 4). The spectrum reveals very weak peaks at 115, 148, and 234 cm^{-1}, weak at 254 and 471 cm^{-1}, moderate at 215 and 299 cm^{-1}, and a very strong peak at 602 cm^{-1}.

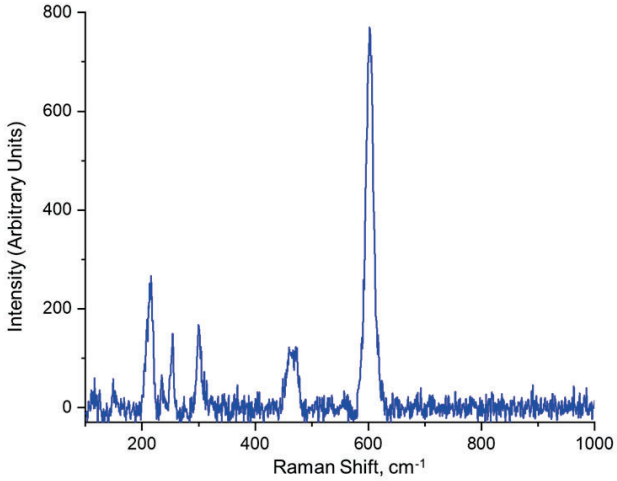

Fig. 4. Raman Spectrum of the CdO/por-CdS/CdS Heterostructure.

The weak peaks at 115, 148, and 234 cm^{-1} could be attributed to low-frequency vibrational modes associated with defects or secondary phases within the heterostructure. These modes are typically not prominent in the Raman spectra of bulk CdS or CdO, suggesting they might originate from surface or interface effects within the porous structure or from a cadmium compound that may have formed during the synthesis process.

The weak peaks at 254 and 471 cm^{-1} indicate the material's intrinsic vibrational modes. The peak at 254 cm^{-1} closely corresponds to the first-order longitudinal optical (LO) phonon mode of cubic CdS, a common feature in its Raman spectrum. While less definitive, the peak at 471 cm^{-1} could potentially relate to second-order vibrational modes of CdS or vibrational modes associated with CdO or complex CdSO phases.

Moderate peaks at 215 and 299 cm^{-1} indicate significant vibrational modes. The peak at 215 cm^{-1} does not align precisely with the typical vibrational modes of CdS or CdO, suggesting it might indicate stress or strain in the crystal lattice or a manifestation of a complex vibrational mode resulting from the heterostructure synthesis. The peak at 299 cm^{-1} aligns more closely with the expected LO phonon mode of cubic CdS, confirming the presence of crystalline CdS in the heterostructure.

The most pronounced feature of the Raman spectrum is the very strong peak at 602 cm^{-1}. This peak is characteristic of the second-order longitudinal optical (2LO) phonon mode of CdS, a harmonic of the 1LO mode. The intensity of this peak points to a significant presence of crystalline CdS within the heterostructure, likely contributing significantly to the vibrational signature. It is essential to consider that a heterostructure and potential interactions between CdO and CdS phases can lead to shifts in peak positions and new modes not seen in the pure phases. Factors such as particle size, crystallinity, and preparation methods could also influence the observed spectrum.

D. XRD Analysis

The X-ray Diffraction (XRD) analysis of the CdO/por-CdS/CdS heterostructure provides crucial insight into the crystalline structure of the present materials (Fig. 5). The diffractogram reveals two distinct peaks: a very high peak at 26.6 degrees, a lower one at 54.5 degrees, and a barely noticeable peak at 60 degrees.

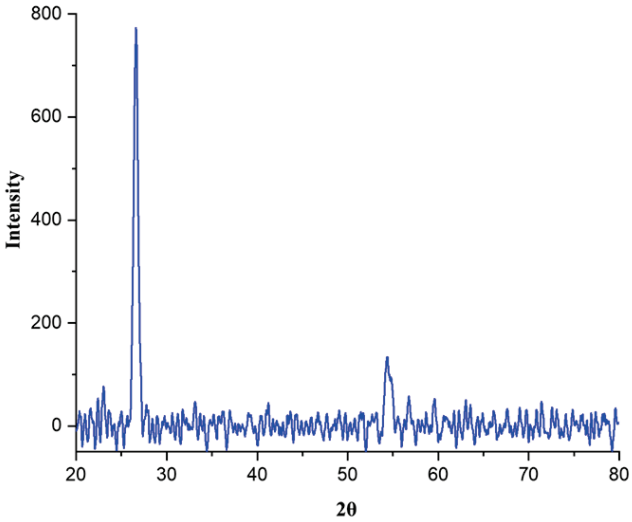

Fig. 5. XRD Spectrum of the CdO/por-CdS/CdS Heterostructure.

The pronounced peak at 26.6 degrees indicates the (002) plane of hexagonal wurtzite CdS. This high-intensity peak suggests a well-ordered crystalline structure and confirms the presence of CdS as a significant phase in the heterostructure. The sharpness of this peak also implies a significant degree of crystallinity within the CdS domains, which is favorable for photoelectric applications due to the efficient charge transport typically facilitated by such crystalline structures.

Although lower in intensity, the peak at 54.5 degrees is likely a higher-order reflection of the same wurtzite CdS, potentially corresponding to the (004) plane. The presence of this peak further corroborates the crystalline nature of the CdS and suggests uniformity in crystal orientation, which is beneficial for the consistency of optoelectronic properties across the heterostructure.

The subtle peak at 60 degrees, while not easily attributable to a specific material phase due to its low intensity, could correspond to a crystalline phase within the CdO or a related oxide compound, possibly indicating the presence of a CdSO phase. However, the low intensity of this peak suggests that if such a phase is present, it is not a principal constituent of the heterostructure or may be poorly crystallized.

Overall, the XRD analysis convincingly suggests that the heterostructure predominantly consists of crystalline wurtzite CdS, with possible minor phases of CdO or CdSO. The crystalline nature of the CdS is advantageous for solar energy conversion, as it typically exhibits high electron mobility and good transport properties, critical for the efficiency of solar cells. The potential presence of other cadmium compounds would also be of interest, as they could introduce additional functionalities to the heterostructure, such as defect states that might aid in charge separation or surface states that could participate in catalytic reactions under illumination.

IV. Discussion

The heterostructure synthesized in our study exhibits a combination of morphological and crystalline features, making it a compelling candidate for solar energy conversion technologies. The presence of a porous CdS layer provides an increased surface area, which is beneficial for absorbing a broader spectrum of solar radiation. As confirmed by our SEM analysis, the porosity of this layer introduces a rough surface texture that can potentially trap light, thereby increasing light absorption efficiency—a critical factor in improving the performance of photovoltaic and photocatalytic systems.

Furthermore, the CdS layer's ability to absorb visible light due to its narrow bandgap makes it particularly attractive for solar energy applications. Efficient absorption of photons in the visible range can generate electron-hole pairs that contribute to generating electric current in solar cells or driving chemical reactions in photocatalytic processes.

The formation of CdO or a complex CdSO structure, as indicated by our Raman and EDX analyses, adds another dimension to the heterostructure's functionality. CdO has a wider bandgap than CdS and can serve as an electron acceptor layer, facilitating charge separation and reducing the recombination of photogenerated carriers. This separation is crucial for increasing the lifetime of charge carriers, thereby enhancing the efficiency of solar energy devices.

The observed strong Raman peak at 602 cm^{-1} confirms the presence of crystalline CdS, known for its high electron mobility. This crystallinity is essential for efficiently transporting charge carriers to the electrodes in photovoltaic cells or to the reactive sites in photocatalytic systems. The X-ray diffraction analysis further supports this, as the sharp peak at 26.6 degrees is characteristic of the (002) plane of hexagonal wurtzite CdS, indicating a well-ordered crystal structure.

Additionally, the heterostructure's morphology—comprised of globular masses with a loose, porous internal structure—may facilitate the diffusion of reactants and products in and out of the material in photocatalytic applications, such as water splitting or CO_2 reduction. This diffusion is crucial for the continuous operation of photocatalytic processes.

In the context of solar cells, the unique structure of the CdO/por-CdS/CdS heterostructure could provide a Z-scheme system where the band alignment promotes a spontaneous flow of electrons from the conduction band of CdS to that of CdO, enhancing the charge separation and transport across the junction. Such a scheme is highly effective in photocatalytic and photoelectrochemical applications, leading to increased quantum efficiency.

Thus, the intricate structure of the CdO/por-CdS/CdS heterostructure, combining the advantageous properties of both CdS and CdO, presents a multifaceted approach to optimizing solar energy conversion. The composition and morphology of the heterostructure are poised to address some of the common challenges in solar energy, such as efficient capture and conversion of sunlight, separation and transport of charge carriers, and catalytic performance in photocatalytic applications. This makes the heterostructure a promising material for the next generation of solar energy conversion devices.

V. Conclusions

The synthesized CdO/por-CdS/CdS heterostructure demonstrates significant potential for applications in solar energy due to its enhanced light absorption and efficient charge carrier dynamics. The electrochemical method used for synthesis is facile and scalable, making it suitable for industrial applications. The heterostructure benefits from the combined properties of CdS and CdO, including a broad absorption range, effective charge separation, and good electron transport capabilities. Analyses such as SEM, EDX, Raman, and XRD collectively indicate the presence of a high-quality heterostructure with favorable morphology and crystallinity for solar energy conversion. Our findings suggest that this heterostructure could be a versatile material for developing high-performance solar cells and photocatalytic systems, offering a pathway toward more efficient solar energy utilization. Future research should focus on device fabrication and performance testing to fully realize the practical applications of this promising material.

***Abstract*—The quest for effective solar energy conversion has led to the development of innovative photovoltaic materials. This study presents the creation of a new heterostructure, $Cd_xTe_yO_z$/CdS/por-ZnO/ZnO, through an approach that combines chemical deposition and electrochemical etching. Structural and compositional analysis was conducted using Scanning Electron Microscopy (SEM) and Energy Dispersive X-ray Spectroscopy (EDX), revealing a heterostructure with unique morphology and multi-element composition. Raman scattering spectra further elucidated the heterostructure's structural integrity and phase purity, with distinct peaks corresponding to γ-TeO_2 and β-CdO. Structural and compositional analysis by SEM/EDX and Raman spectroscopy confirms the successful formation of a CdxTeyOz/CdS/por-ZnO/ZnO heterostructure with a multilayer architecture and mixed-oxide phases. These results establish a fabrication route and structural baseline for subsequent optical and electronic characterization toward photovoltaic and optoelectronic applications.**

Keywords— photovoltaic materials, heterostructure, $Cd_xTe_yO_z$, CdS, por-ZnO, ZnO, chemical deposition, electrochemical etching, SEM, EDX, Raman spectroscopy, oxygen annealing, solar cells, optoelectronics

I. Introduction

Solar energy, characterized by its sustainability and inexhaustibility, plays a vital role in the evolution of distributed energy networks serving a variety of applications in the civil and defense sectors [1, 2]. The need for efficient conversion of solar energy into electrical energy has spurred research and development of advanced materials and technological methodologies [3, 4]. For example, the deployment of silicon photovoltaics has historically dominated the solar energy sector due to their proven efficiency and scalability [5, 6]. However, environmental and economic issues associated with silicon photovoltaic elements have led to the exploration of alternative materials, such as CdTe [7, 8] and InP [9, 10], Ga_2O_3 [11, 12], which offer comparable efficiency with potentially less life-cycle impact. Meanwhile, developing thin-film technologies and perovskite solar cells represents a paradigm shift towards inexpensive, high-efficiency alternatives to conventional photovoltaic systems [13]. These developments underscore the dynamic landscape of solar energy research, where the search for sustainable, efficient, and economically viable solar cells continues to stimulate innovation in materials science and engineering.

In this context, heterostructures have attracted significant attention due to their unique properties and advantages over binary semiconductors [14, 15]. Heterostructures, consisting of multiple layers of different materials, provide improved charge separation and transport, excellent optical properties, and a tunable band gap [16, 17]. These features not only enhance the efficiency of solar cells but also expand their application for a broader spectrum of photovoltaic and photoelectrochemical applications [18]. The strategic design of heterostructures allows for optimizing light absorption, charge carrier mobility, and stability, thereby addressing some fundamental challenges in solar energy conversion [19].

II. Experiment

A. Substrate Preparation

Hydrothermally grown zinc oxide (ZnO) monocrystals were selected as the substrate material due to their high crystalline quality and suitability for surface modification. We applied surface texturing to enhance the adhesion of subsequent layers and increase the surface area for improved mechanical interlocking. This was achieved through anodic electrochemical etching, creating a specific micro-relief on the ZnO surface. The etching was conducted in a solution containing hydrochloric acid, water, and ethanol in a volume ratio 2:1:1, under a constant voltage of 10 V for 5 minutes. Illumination from an Osram XBO xenon lamp with a power of 250 W, positioned 10 cm away from the semiconductor surface, was applied to enhance the process by facilitating the generation of electron-hole pairs in ZnO, easing the etching. The resulting micro-relief contains terraces, steps, and pores, optimizing the substrate for better layer adhesion, light absorption, and scattering, which is crucial for fabricating a high-efficiency heterostructure.

B. Formation of CdS on the surface of por-ZnO/ZnO

Following substrate preparation, the deposition of the CdS layer was critical for establishing the heterojunction, affecting the optical and electronic properties of the solar cell. In distilled water, a solution was prepared from 0.2 M cadmium

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

chloride, 0.2 M thiourea, and 5 M ammonia. This mixture was stirred at 80°C for 20 minutes to ensure uniformity. The textured ZnO substrate was immersed in this solution for 5 hours and optimized to achieve a uniform CdS layer. Subsequent rinsing in distilled water removed residual chemicals, ensuring the purity of the CdS layer.

C. Formation of $Cd_xTe_yO_z$ on the CdS/por-ZnO/ZnO Substrate

For the deposition of $Cd_xTe_yO_z$ oxides on the CdS/ZnO substrate, the successive ionic layer adsorption and reaction (SILAR) method was employed over five cycles. This process allowed for layer-by-layer controlled deposition of materials, achieving a finely structured heterostructure. The SILAR cycle involved immersion in a Na_2TeO_3 solution for the adsorption of tellurium ions, rinsing in H_2O_2 to remove excess ions, immersion in a $Cd(NO_3)_2$ solution for the adsorption of cadmium ions, and a final rinse in H_2O_2 to remove non-adsorbed ions.

D. Oxygen Annealing

After deposition, oxygen annealing was conducted at 150°C for 20 minutes in atmospheric air using a JetFirst diffusion furnace. This step aimed to saturate the layers with oxygen, which is crucial for the passivation of surface defects and enhancement of charge carrier mobility. The additional impact of external conditions over three months tested the natural stability and durability of the heterostructure.

E. Characterization

The morphology and elemental composition of the synthesized structures were analyzed using an SEO-SEM Inspect S50-B scanning electron microscope and energy-dispersive X-ray spectroscopy (EDX) with an AZtecOne spectrometer. Raman scattering spectra were obtained using a DRON-3M spectrometer with 532 nm excitation, a spectral resolution of ~1 cm^{-1}, and a temperature-controlled cryostat system.

III. Results

A. SEM Analysis

Scanning Electron Microscopy analysis revealed a distinct surface morphology characterized by a heterogeneous distribution of elements (Fig. 1). The micrograph contrasts the textured background and separate, darker areas, indicating material deposition or surface features. The dark areas have irregular shapes, ranging from sub-micrometer to several micrometers in diameter. These formations suggest an uneven growth pattern, which may be related to localized conditions during the material synthesis or post-synthesis processing stages.

The background texture consists of stripes and granular elements, corresponding to the micro-relief obtained during the electrochemical etching. The granular aspects of the surface are interspersed with terraces and steps, potentially useful for light absorption and scattering, crucial for solar cell applications.

Furthermore, the shadowing effects observed around the darker areas suggest some topographic dispersion, indicating that these areas are raised above the general plane of the substrate. This relief could potentially affect the light-matter interaction on the surface, a factor of significant interest for optimizing the optical properties of solar cells.

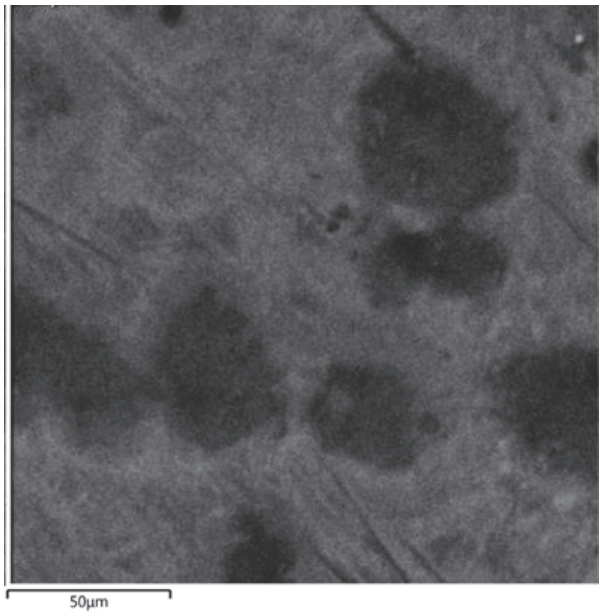

Fig. 1. SEM image of the $Cd_xTe_yO_z$/CdS/por-ZnO/ZnO heterostructure surface.

B. EDX Analysis

Energy-dispersive X-ray Spectroscopy (EDX) provided quantitative insight into the elemental composition of the $Cd_xTe_yO_z$/CdS/por-ZnO/ZnO heterostructure (Table 1, Figure 2). As expected, Tellurium (Te) atoms constitute 21.53% of the heterostructure, indicating significant inclusion in the material, considering its role in forming the $Cd_xTe_yO_z$ matrix. Oxygen (O) is the most abundant element with an atomic percentage of 33.41%, reflecting the oxide components of the heterostructure, as well as the oxygen annealing process, which likely contributed to its prevalence. Sulfur (S), making up 11.65% of the atomic composition, aligns with the presence of the CdS layer, which ideally should form a stoichiometric compound with cadmium. However, the atomic percentage suggests a non-stoichiometric ratio, potentially indicating sulfur vacancies or excess cadmium in the CdS layer.

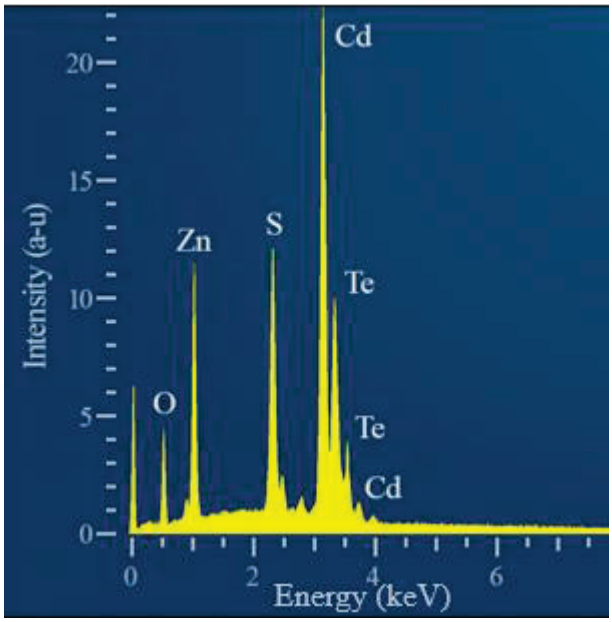

Fig. 2. EDX- spectrum of $Cd_xTe_yO_z$/CdS/por-ZnO/ZnO.

TABLE I. COMPONENT COMPOSITION OF THE OF THE $CD_XTE_YO_Z$/CDS/POR-ZNO/ZNO HETEROSTRUCTURE

Element	Atom, %
Te	21.53
O	33.41
S	11.65
Zn	1.15
Cd	32.26

Zinc (Zn) atoms are present at least 1.15%, which is expected since the ZnO layer serves as the substrate material, not the primary active layer of the heterostructure. Cadmium (Cd) has a significant presence with 32.26% of the atomic composition, expectedly, as it plays a crucial role in both the CdS and $Cd_xTe_yO_z$ layers. The high percentage of Cd underscores its importance in the overall structure, contributing to the electronic properties of the heterojunction.

Thus, the EDX analysis confirms the successful formation of the $Cd_xTe_yO_z$/CdS/por-ZnO/ZnO heterostructure with a complex multi-element composition. The elemental ratios indicate a degree of non-stoichiometry, which may affect the electronic and optical properties of the heterostructure. These findings lay the groundwork for further evaluations of design and efficiency for optimizing the material for photovoltaic applications.

C. Raman Analysis

Raman spectroscopy analysis of the $Cd_xTe_yO_z$/CdS/por-ZnO/ZnO heterostructure provides insights into its structural composition (Fig. 3).

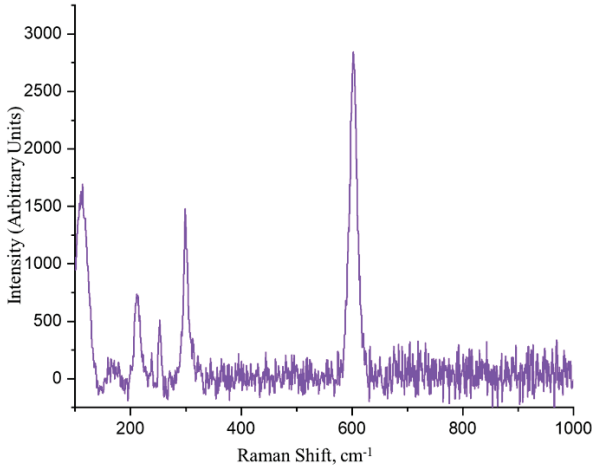

Fig. 3. Raman- spectrum of $Cd_xTe_yO_z$/CdS/por-ZnO/ZnO.

The most pronounced peak at 602 cm^{-1} is primarily attributed to the stretching vibrations of TeO_4 units, characteristic of the γ-TeO_2 phase. This peak indicates a significant content of tellurium oxide, particularly involving TeO_4 self-mot polyhedra within the $Cd_xTe_yO_z$ structure. The intensity and position of this peak suggest the degree of crystallinity and the presence of defects or impurities affecting the TeO_4 structure.

A strong peak at 300 cm^{-1} is closely associated with the γ-TeO_2 phase, representing a combination of vibrational modes. This peak indicates a structured γ-TeO_2 environment, with its intensity and spectral position reflecting this phase's stoichiometry and crystalline quality in $Cd_xTe_yO_z$.

The peak at 254 cm^{-1} corresponds to the transverse optical (TO) mode of β-CdO. This medium-intensity peak indicates the inclusion of cadmium oxide in the structure and sheds light on the nature of the Cd-O bond within the $Cd_xTe_yO_z$ heterostructure.

A medium-intensity peak at 213 cm^{-1} is best attributed to the E (longitudinal optical (LO)) mode in TeO_2, indicating a distinct vibrational mode associated with this specific phase of tellurium oxide in the material. This peak provides insights into the crystallinity and phase purity of the TeO_2 component in $Cd_xTe_yO_z$.

Finally, a weak peak at 112 cm^{-1} is associated with Ag modes involving Te-O-Te bonding. This peak in the spectrum indicates the presence of tellurium in a specific bonding environment, contributing to the structural stability of the material.

The synthesis of the $Cd_xTe_yO_z$/CdS/por-ZnO/ZnO heterostructure, as detailed in this study, reveals a complex mechanism of formation facilitated by a combination of chemical and electrochemical processes. The experimental data underscore the successful formation of a dense oxide layer, showcasing the presence of binary oxides such as TeO_2 and various TeO_x units on the surface. This indicates a multi-stage evolution of the structure where initial formations of CdO and TeO_4 evolve into TeO_2 and TeO_3 as they become saturated with oxygen, which is a critical component in forming the ternary oxides $Cd_xTe_yO_z$. These oxides are integral to the heterostructure, containing only Cd-O and Te-O bonds without direct Cd-Te linkages.

The direct application of the $Cd_xTe_yO_z$ layer onto the ZnO substrate may result in insufficient adhesion due to the weak interaction and incoherence between their crystal lattices. To address this challenge, we introduced a CdS buffer layer, which demonstrated an enhanced affinity and coherency with the lattice structures of the synthesized materials CdO, $CdTeO_3$, and $CdTe_3O_8$. This CdS buffer layer serves as a reliable interface for the subsequent oxide layers and facilitates the formation of a transition layer of CdO, which is essential for the subsequent formation of $Cd_xTe_yO_z$.

The application of the SILAR method was a pivotal aspect of our synthesis process. SILAR operates on the principle of adsorbing ionic particles from a solution onto the substrate surface, triggering a localized chemical reaction that results in the formation of an insoluble product. The selection of the primary precursor is crucial, as the initial thin film acts as the adsorption center for further material deposition. Moreover, the process of washing the sample to remove excess and weakly bonded atoms is a critical step to ensure good film adhesion to the substrate.

The potential applications of heterostructures are broad, ranging from high-efficiency solar cells to optoelectronic devices, where their layered structure and individual properties can lead to improved performance characteristics compared to traditional materials. The ability to manipulate light absorption, charge carrier dynamics, and interfaces at the molecular level offers a significant advantage in developing

next-generation photovoltaic devices. The enhanced light-matter interaction of the heterostructure, facilitated by its unique morphology and composition, may lead to devices with higher photovoltaic conversion efficiency and better stability under various environmental conditions.

Future research prospects include exploring doping strategies to modulate the electrical properties of the heterostructure, as well as incorporating additional layers or interfaces to improve charge separation. Investigating the long-term stability and performance of the heterostructure in real-world operating conditions will also be critical. Furthermore, attention to the scalability of the manufacturing process is needed to assess the commercial viability of the heterostructure for industrial applications. Finally, a comprehensive life cycle assessment would be helpful to ensure that the environmental impact of heterostructure production remains within sustainable limits, aligning with the broader goals of renewable technology advancements.

IV. Conclusions

We fabricated a multilayer CdxTeyOz/CdS/por-ZnO/ZnO heterostructure by combining chemical deposition, electrochemical texturing, and SILAR. SEM/EDX and Raman spectroscopy verify the multilayer composition (Cd, Te, O, S, Zn) and the presence of TeO_2- and CdO-related modes, indicating the formation of mixed tellurium–cadmium oxides on CdS/ZnO. While the present study focuses on synthesis and structural/compositional verification, future work will report the optical (PL/absorption) and electronic (I–V/photocurrent) properties under controlled conditions.

Abstract*— The paper emphasizes the urgent need for Ukraine's metallurgy sector, particularly at PJSC "Zaporizhstal," to replace outdated technologies with modern, sustainable steel production methods as part of a global "green transition". The investigation encompassed field measurements, followed by rigorous data processing and analysis. A comparative analysis was conducted to enhance the findings. The study compares the electricity consumption at two different steel production methods: (I) iron ore sintering process (IOSP) with an aspiration system + blast furnace (BF) + an open-hearth furnace (OHF) smelting; (II) Midrex process + electric arc furnaces (EAF) smelting. The analysis revealed that the specific energy consumption (SEC) varies significantly across different processes: the Electric Arc Furnace (EAF) requires the highest at approximately 340 kWh/t, followed by the Midrex process at 85 kWh/t. The Open Hearth Furnace (OHF) and Blast Furnace (BF) show lower energy demands at around 4 kWh/t and 3.3 kWh/t respectively, while the Sintering Plant (SP) consumes about 33 kWh/t. It is evident that the "IOSP + BF + OHF" method generates substantially higher CO2 emissions than the more efficient "Midrex + EAF" approach. The IOSP is among the most energy-intensive processes, whereas the BF requires less energy. The OHF, though consuming relatively little energy, is less attractive due to its inefficiency. While the Midrex process demands more energy than traditional methods, it compensates with substantial environmental advantages by emitting less CO2. The Electric Arc Furnace (EAF), despite its high energy requirements, excels in the efficient and flexible recycling of steel scrap. Research indicates that adopting advanced technologies like Direct Reduction (DR) via the Midrex process, followed by pellet melting in an EAF, is a crucial step toward lowering emissions and enhancing the energy efficiency of modern steelmaking practices.

Keywords*—green transition in metallurgy, steelmaking methods, specific energy consumption, CO_2 emissions, energy efficiency, Midrex process, electric arc furnaces.

I. Introduction

There is an acute need to transition to green production methods with a low carbon footprint worldwide. This is particularly relevant for the metallurgical industry, which is energy- and carbon-intensive [1]. Global trends toward green steel production methods are being considered [2]. These issues are relevant for many countries and this will also affect Ukraine in the period from 2025 to 2050 [3]. Reforming the steel industry is closely linked to the restructuring of the energy sector for the production of "green" electricity generated by alternative methods (solar [4], bioenergy [5], wind [6], etc.) without the use of hydrocarbons as feedstock. This is especially significant for PJSC "Zaporizhstal," which still uses outdated iron ore sintering process (IOSP) + blast furnace (BF) production and open-hearth furnace (OHF) methods. The project to construct new production facilities based on Midrex and Electric Arc Furnace (EAF) technology will be particularly relevant [7].

The metallurgical industry is diverse and energy-intensive, with various technologies used for steel production. These include the IOSP combined with a BF, OHF, Midrex direct reduction (DR) technology, and EAF, each with distinct methods and energy consumption profiles. The paper [8] presents calculations determining the amount of energy consumption in metallurgical processes in China. It is noted that the comprehensive energy consumption per tonne of crude steel has significantly decreased from 48.2 GJ in 1980 to 16.1 GJ in 2023. Despite this improvement, the total energy consumption on example of China's iron and steel industry has risen from 1.76×10^9 GJ in 1980 to 1.65×10^{10} GJ in 2023 due to the ongoing increase in crude steel production [9]. Theoretical calculations of electricity consumption do not take into account equipment wear [10], the state of the power system and the quality of electricity [11], fluctuations in the characteristics of raw materials and the changing range of smelted iron and steel [12]. Therefore, preference should be given to direct measurements and direct calculations of energy consumption based on the data taken [13].

The objective of this study is to compare these technologies, with a particular emphasis on their energy efficiency and operational parameters. The IOSP, including sintering plants with aspiration systems, and BF are

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

conventional and widely used methods. The energy consumption for IOSP is approximately 33 kWh/t, while a blast furnace requires about 3.3 kWh/t. On the other hand, the OHF, which is currently less common due to high energy consumption and a prolonged process, requires approximately 4 kWh/t of steel produced. Modern technologies, such as the Midrex process, which uses hydrogen as a reductant, offer a more environmentally friendly alternative. The energy consumption for Midrex is about 85 kWh/t. The EAF, known for its high efficiency and flexibility, consumes approximately 340 kWh/t. Additionally, modern technologies help reduce CO_2 emissions, which is crucial given the tightening environmental regulations and sustainable development requirements. The evaluation of various steel production techniques encompasses considerations such as maintenance costs, capital expenditures for infrastructure, and environmental impacts. Consequently, this comparison will help pinpoint the most efficient and economically sustainable methods for modern steel manufacturing.

The IOSP and BF, although long-used, are continuously evolving to improve energy efficiency and reduce emissions. Study [12] have shown that optimizing the IOSP and enhancing BF efficiency can significantly impact overall energy consumption and emissions. For example, applying new temperature and charge composition control technologies reduces energy costs and improves the final product's quality. Implementing heat recovery systems and improving aspiration systems also helps reduce harmful emissions into the atmosphere. Research on OHF technology [14] highlights its inefficiency compared to modern technologies, but it is still used in some regions due to existing infrastructure. OHF require significant maintenance and modernization costs, and their energy consumption significantly exceeds modern alternatives, considering hydrocarbon consumption as energy carriers. However, in some countries where industrial modernization is slower, these furnaces remain an essential part of the metallurgical complex.

The Midrex process, especially with hydrogen integration (Midrex), represents a significant breakthrough in reducing CO_2 emissions. Literature data [15] indicates that using hydrogen in the reduction process can reduce the carbon footprint of steel production. Using hydrogen as a reductant instead of traditional natural gas significantly reduces greenhouse gas emissions. Moreover, Midrex technology is actively researched in the context of increasing demand for environmentally friendly technologies and renewable energy sources. However, the economic efficiency of this technology depends on the availability and cost of hydrogen and infrastructural investments. The EAF, despite high energy consumption, also benefits from advances in energy technologies and processes [7–9, 16], making it competitive in regions with abundant electricity. Through the comparison of these technologies, we can identify the most effective and economically viable approaches for contemporary steel production, taking into account energy use, environmental considerations, and operational performance.

II. Research Methodology, Materials and Equipment

The methodology of the study involved a comprehensive and multi-stage approach to analysing the energy consumption and efficiency of different steelmaking technologies, which enabled all key aspects of the processes to be covered: (a) field measurements and data collection; (b) data processing and analysis; and (c) comparative analysis.

(a) Field measurements and data collection. The basis of the study was accurate measurements of energy consumption at PJSC "ZAPORIZHSTAL" enterprise. To ensure a high level of data accuracy and minimize errors, a wide range of modern measuring devices and specialized metering systems was used. In particular, for obsolete technologies, which continue to be used at the enterprise, the work was organized with the help of Elster Alpha A1140-10-RAL-BW-4T meters. These meters, due to their high accuracy and reliability, were integrated into the plant-wide energy metering system "Alpha Center". This system, developed by the company's internal IT department, provides the ability to collect and analyze data in real time. "Alpha Center" allows not only to read metering devices at electrical substations but also to build phase portraits (Fig. 1) of energy consumption, which significantly expands the analysis capabilities. In particular, the system provides the ability to track dynamic changes in network load (Fig. 2, and Fig. 3), which is important for understanding peak power consumption.

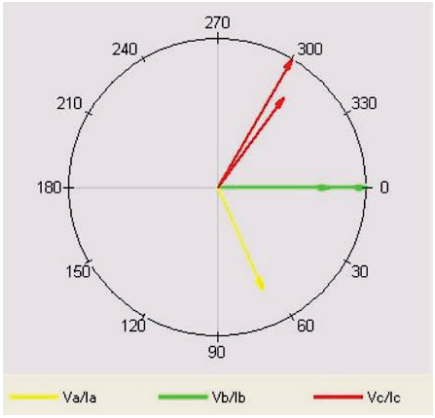

Fig. 1. Picture from the screen of the "Alpha-Center" software by phase portrait of electricity consumption (*Va* and *Ia*, *Vb* and *Ib*, *Vc* and *Ic* – voltage and current of phase "a", "b" and "c" respectively).

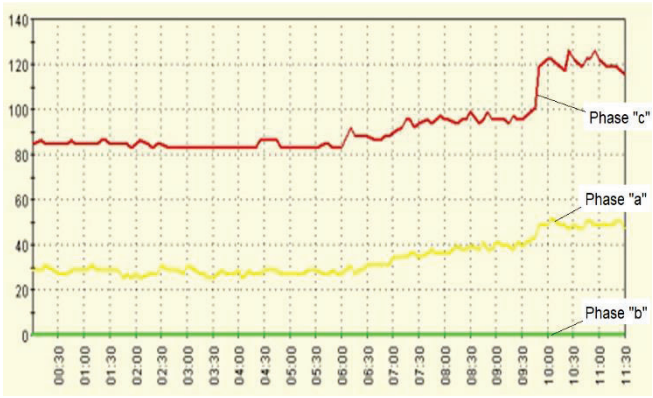

Fig. 2. Hourly (current time, h:min, – horizontally) dynamic monitoring of load changes (active power consumption, kW, – vertically) on the network of the IOSP measured by the "Alpha Center" software.

Data were collected from key substations serving the sintering process and aspiration plants (substations nos. 3, 10, 12, 16, and 19), as well as substations for blast furnaces (substations nos. 21, 30, and 45) and open-hearth furnaces (substations nos. 76, 78, and 51). All the collected data was aggregated in the "Alpha Center," which made it possible to

generate a consolidated report presenting a complete picture of energy consumption at all stages of production. In addition, production indicators were monitored as part of the internal development program of "Steel-Rolling" software, which allowed the energy consumption data to be supplemented with information on product output. The "Steel-Rolling" software is an internal development program aimed at measuring and evaluating production processes, specifically sintering, iron smelting, and steel pouring. The resulting data was generated into Excel reports for further analysis and comparison with reference data.

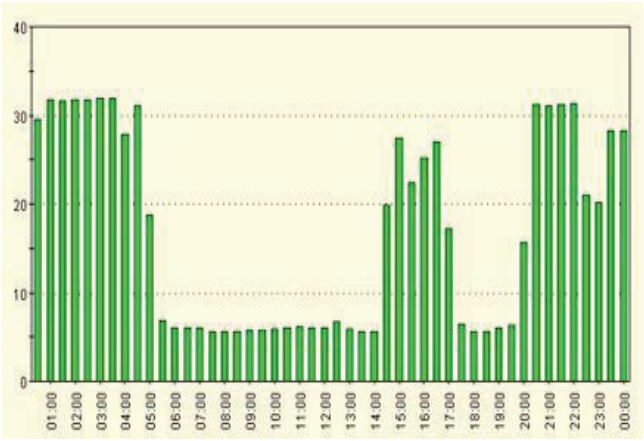

Fig. 3. Hourly (current time, h:min, – horizontally) dynamic monitoring of changes in total active load (total active power, kW, – vertically) on the network of the BF measured by the "Alpha Center" software.

Reference data from equipment manufacturers were used to assess the energy consumption of the new technology, which is planned to be introduced at the enterprise as part of the transition to "green" production. In particular, for the Midrex and EAF technology, data from “Midrex” and “Danieli” companies were provided. These companies, which have extensive experience in equipment development, provided data adapted to the conditions of PJSC "ZAPORIZHSTAL". The data included predicted energy consumption values and allowed for an accurate comparative analysis with the actual data obtained at the plant.

(b) Data processing and analysis. The processing of the measurement data constituted a crucial phase of the study.. During this phase, a thorough review of all the data collected was performed to determine the energy efficiency of each of the steel production methods used. An important aspect of the analysis was the comparison of actual data collected through the "Alpha Center" and "Steel-Rolling" systems with reference data from equipment manufacturers. This enabled an in-depth analysis of the efficiency of current production processes and identified possible reserves for energy efficiency improvements. The analysis took into account the distribution of energy consumption across different process stages, which allowed us to identify the most energy-consuming processes and propose ways to optimize them.

The assessment included a calculation of specific electricity consumption rates per ton of produced products. This calculation was performed using the methodology developed at the enterprise within the framework of ISO 50001 international standard certification, which ensured high accuracy and reliability of the results obtained. The main efficiency indicator was the specific energy consumption rate calculated by the equation:

$$S_a = C_a / P_o, \quad (1)$$

were S_a – actual specific consumption for the technology (kW/t); C_a – actual energy resource consumption (kW); P_o – amount of produced output (t).

(c) Comparative analysis. At the final stage of the study, a comprehensive comparative analysis of two methods of steel production was carried out: the traditional method, which uses outdated technologies, and the new method, which is planned to be introduced as part of the "green" transition. The analysis included an assessment of the methods in terms of their energy efficiency, environmental impact, and economic feasibility. The comparison was based on data obtained during measurements and reference data provided by equipment manufacturers.

The comparison highlighted the key advantages and disadvantages of each production method. Based on the analysis, specific measures to reduce energy consumption were proposed, including optimization of technological processes, equipment modernization, as well as introduction of advanced methods of energy management. As a result of this study, conclusions were made that will help PJSC "ZAPORIZHSTAL" not only to increase energy efficiency of production, but also to strengthen its position in the market by switching to more environmentally friendly technologies, which is especially important in the context of increasing requirements for sustainable development and carbon footprint reduction.

III. Results and Discussion

The combination of the IOSP + BF process with the OHF leads to significantly higher CO_2 emissions compared to the Midrex + EAF technology, as demonstrated in Table 1. Specifically, the IOSP + BF + OHF process produce 2430 kg/t of emissions per ton of steel, while Midrex + EAF generates only 613 kg/t of emissions per ton of steel. This indicates that the Midrex + EAF technology is significantly more environmentally friendly and contributes to reducing the carbon footprint of steel production. The experiments were conducted under real-world conditions, confirming the practical significance of the results obtained. These data demonstrate the importance of implementing modern technologies, such as Midrex, to reduce the environmental impact of steelmaking processes.

Table I. Calculation of Emissions per Ton of Steel

Production type	Emissions (kg/t)
IOSP+BF+OHF	2430
Midrex + EAF	613

Different steel production technologies have significant differences in energy consumption. The IOSP process with aspiration systems is one of the most energy-intensive, consuming about 33 kWh/t of steel (Table 2). This is due to the high costs of raw material preparation and maintaining the sintering process. The BF, typically used alongside the sintering process, requires 3.3 kWh/t of steel. Although this is much lower than IOSP, the overall energy costs remain high. The OHF, though less common today, requires relatively little energy — 4 kWh/t of steel. However, its inefficiency and prolonged process make it less attractive for modern production.

TABLE II. ENERGY INTENSITY OF DIFFERENT IRON AND STEEL PRODUCTION

Technology	Energy Consumption (kWh/t)
IOSP with Aspiration Systems	33
BF	3.3
OHF	4
Midrex	85
EAF	340

The modern Midrex technology, which uses hydrogen as a reductant, demonstrates high energy efficiency with a specific energy consumption of 85 kWh/t of steel. This makes it attractive in terms of environmental cleanliness and emission reductions. The EAF consumes 340 kWh/t of steel. Despite higher energy consumption compared to some other technologies, EAF is flexible in using secondary raw materials, contributing to a circular economy. When studying the IOSP+BF process and OHF technology (Fig. 4), it was found that this outdated method has high CO_2 emissions and significant energy consumption (Table 3). This method has a negative environmental impact due to the large amount of CO_2 emissions. Midrex (Fig. 5) and the EAF (Fig. 6), on the other hand, are modern technologies that show low CO_2 emissions but high energy consumption (Table 4). These methods have higher energy consumption and lower environmental impact, making them attractive for modern production conditions. Practical applications – the studies were conducted under real production conditions, giving them practical significance.

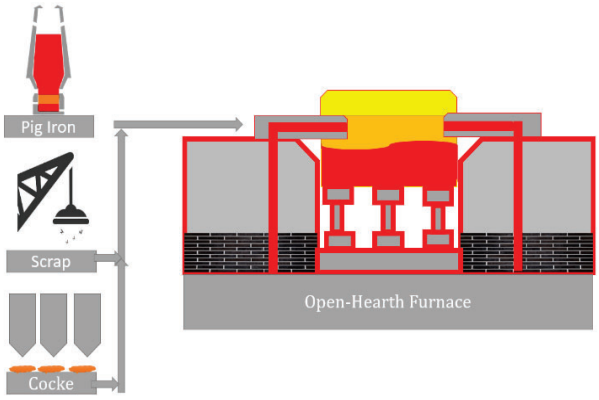

Fig. 4. Open-Hearth Steel Production Process.

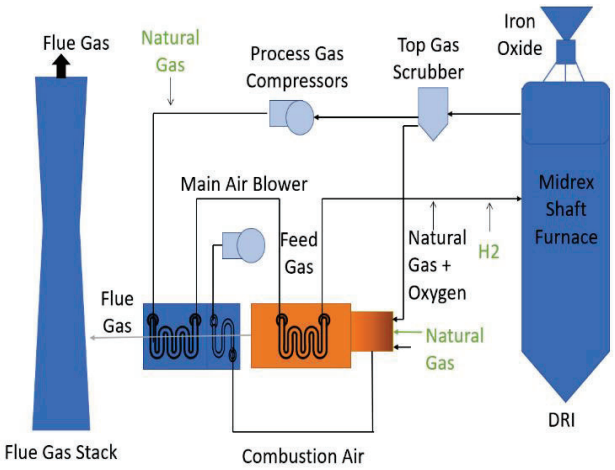

Fig. 5. Diagram of the Midrex process.

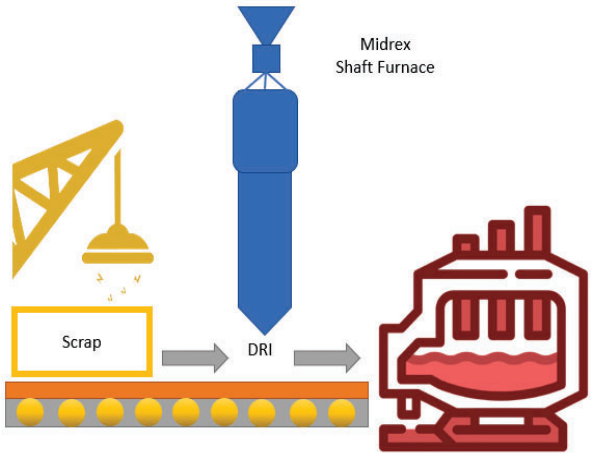

Fig. 6. Diagram of EAF charging process.

Comparison indicates differences in energy consumption (Fig. 7), but each method has its advantages and disadvantages. These research results can be used to make decisions about the optimal steel production method for a specific enterprise, taking into account energy efficiency and environmental requirements. Considering the growing requirements for reducing CO_2 emissions and optimizing energy use (Table 5), modern technologies such as Midrex and EAF have significant potential to increase the competitiveness and sustainability of steel production.

TABLE III. MAJOR ENERGY CONSUMERS IN THE SINTERING-BLAST FURNACE PROCESS AND OPEN-HEARTH FURNACE (FOR IRON ORE AND STEEL)

Process	Energy Consumer	Energy consumption (kWh/t)
IOSP	Crushing and sorting of ore	4.3
	Ore drying	5
	Mechanical mixers	3
	Conveyors and transporters	2.7
	Sintering belts	8
	Dust collectors and gas cleaners	10
BF	Air and oxygen injection	0.6
	Fuel feeding	0.55
	Heating systems	0.5
	Elevators and conveyors for raw materials	0.4
	Cooling systems	0.375
	Control and automation systems	0.475
	Gas cleaning and utilization systems	0.4
OHF	Air and gas supply systems	0.3
	Mechanical equipment for loading and unloading materials	1.3
	Cooling systems	0,8
	Gas cleaning and recirculation systems	0,6
	Control and automation systems	1

TABLE IV. MAJOR ENERGY CONSUMERS IN MIDREX TECHNOLOGY (FOR DRI)

Energy Consumer	Energy Consumption (kWh/t)
Hydrogen Electrolyzes	3000
Blowers and Compressors	12
Heating Systems	15
Gas cleaning and recirculation systems	7
Control and automation systems	2
Raw material handling systems	4

TABLE V. MAJOR ENERGY CONSUMERS IN ELECTRIC ARC FURNACE (EAF) TECHNOLOGY (FOR STEEL)

Energy Consumer	Energy Consumption (kWh/t)
Main electric arc process	300
Electrode feeding and regulation	10
Gas cleaning	10
Cooling systems	5
Loading and unloading mechanisms	10
Monitoring and control systems	5

The analysis of the data from the three tables indicates that the Midrex technology for direct reduced iron (DRI) production is the most energy-intensive, with hydrogen electrolysis consuming 3000 kWh/t. The Electric Arc Furnace (EAF) also shows significant energy demands, especially for the main electric arc process, which requires 300 kWh/t. In comparison, the Blast Furnace (BF) and Open-Hearth Furnace (OHF) processes are considerably less energy-intensive, with the highest consumption around 10 kWh/t for gas cleaning systems in the IOSP process. Therefore, while technologies like Midrex and EAF offer environmental benefits, they require substantially more energy compared to traditional methods.

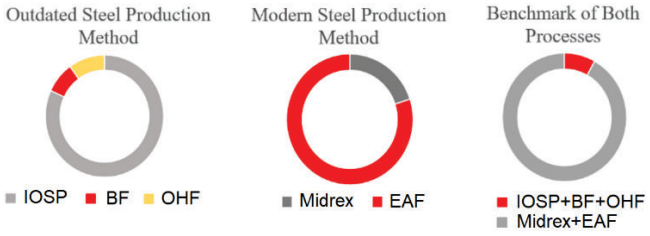

Fig. 7. Comparative energy consumption diagram.

Thus, the outdated method, the IOSP (Fig. 7a), which is used to prepare ore materials for blast furnace smelting, occupies the most share of energy consumption. According to the obtained data, its share is 83%, with the blast furnace process at 7% and the open-hearth process at 10%. In the modern method (Fig. 7b), the primary consumer is the EAF, which accounts for 80% of the complex's energy consumption. The benchmark (Fig. 7c) indicates also that the modern method consumes 90% of the energy compared to the outdated method, indicating that the modern method is 9 times more energy-intensive.

IV. CONCLUSION

The study demonstrated that transitioning from the traditional IOSP + BF + OHF process to the modern Midrex + EAF process leads to a significant reduction in CO_2 emissions – by as much as 75%, from 2430 to 613 kg per ton of steel. Despite a slight increase in electricity consumption, the new technology allows for a considerable decrease in the carbon footprint of production, making it more environmentally friendly and responsible. The comparison of steel production methods revealed significant differences in energy consumption. The open-hearth process, outdated and less efficient than EAF, is still used for the production of certain steel grades. The Midrex process offers a more energy-efficient and environmentally friendly alternative to the traditional IOSP + BF + OHF steelmaking route, particularly in the face of stricter environmental regulations.

The adoption of modern technologies, such as Midrex and EAF, is crucial for the steel industry to reduce its carbon footprint and improve energy efficiency, ensuring a sustainable future.

***Abstract*—The femoral stem design and cementation technique are among the most important factors determining the long-term success of total hip arthroplasty (THA), especially in patients with low bone quality. Cemented femoral stems can be force-closed or shape-closed, and each type demonstrates unique biomechanical attributes and clinical results. This study focuses on the comparative biomechanical analysis of force-closed versus shape-closed cemented femoral stems, which compares their structural and fatigue properties under physiologically relevant loading conditions. A three-dimensional structural analysis is performed on two cemented femoral stem designs such as i) a collarless, force-closed stem and ii) a collared, shape-closed stem. Static structural and fatigue analysis simulations were conducted for steady loading and a dynamic response. The results were examined for certain key parameters, including von Mises stress, total deformation, strain, and safety factor. Under static loading, the shape-closed design demonstrated superior mechanical performance concerning lower von Mises stress (44.7 MPa vs. 112.5 MPa), strain (2.84×10^{-4} vs. 5.54×10^{-4}), and deformation (6.27×10^{-3} mm vs. 7.76×10^{-3} mm). Dynamic load simulations also showed similar trends in the results. The fatigue analysis corroborated this enhanced performance of the shape-closed stem, revealing a factor of safety more than 2 times higher for every loading condition from the analysis. A femoral stem with a shape-closed design with a biomechanically optimized collar and control of proximal geometry can provide higher stability and fatigue resistance compared with a force-closed design. The results, therefore, imply that shape-closed stems should provide greater durability than forced-closed stems in the press-fit condition of cemented THA, particularly when cementing techniques are not adequate.**

Keywords— ***Total Hip Arthroplasty, Shape-Closed Stem, Force-Closed Stem, Femoral Stem Design, Fatigue Analysis.***

I. Introduction

Total Hip Arthroplasty (THA) is the most frequently performed and effective orthopedic procedure, used to restore movement and reduce pain in patients with advanced hip joint diseases such as osteoarthritis, rheumatoid arthritis, and femoral neck fractures. With increasing life expectancy and activity of patients, long-term durability and biomechanics of hip implants are of utmost importance. The optimal femoral stem is of utmost importance for the success of THA, as it is involved in load transfer, stability of the joint , and the survival of the prosthesis [1]. While femoral stems can be divided into multiple categories, cemented stems continue to be used frequently, especially in patients with poor bone quality [2].

About the biomechanical behavior, cemented femoral stems can be mainly classified into two groups: force-closed and shape-closed stems [3]. Force-closed stems, usually without a collar and polished, are meant to subside to a certain degree in the cement mantle, allowing even load transfer and durable anchorage. They are frequently used because they are versatile, easily modified, and not too demanding surgically. These stems are in more prevalent use, they perform well in myriad patients with ease of revision should it be required, and have excellent long-term findings, especially in the elderly [2] [4]. While long-term registry data shows that force-closed designs like the Exeter stem demonstrate superior survival rates compared to shape-closed designs such as the Lubinus stem (73.9% vs. 65.5% over 25 years), the reasons for this difference are not clearly stated [4]. Force-closed stems have their downsides as well. A greater amount of cement can initiate stress shielding and sometimes result in progressive subsidence or micromotion, ultimately causing the long-term excessive displacement of the prosthesis, particularly in young and old patients or those with higher physical activity [5] [6]. Shape-closed stems frequently exhibit a greater proximal geometry that is more anatomical and larger. They are designed to include a collar to reduce micromotion and improve proximal load transfer by closely matching the endosteal geometry of the femoral canal. Although they show lower aseptic loosening and superior initial stability, they have several limitations. These include increased intramedullary pressure during implantation, which may precipitate bone cement implantation syndrome (BCIS). They are additionally sensitive to cementing technique and can show loosening over time as a result of non-uniform application of forces and wear [2] [3] [5].

The factors to consider in hip replacement design are material selection, energy efficiency and force balance, and thermal management and material durability, to achieve a

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

functional, durable, and easy-to-use solution [7]. Few novel designs used special plastic liner, ceramic head with metal backing or porous titanium cup [8]. But these design do not involve modification or optimization of the implant stem. The difficulty for the design is the balance of initial enough fixation, long-term stability, and safe cementation. However, limited comparative biomechanical studies have been reported in the literature investigating the biomechanical behaviors, such as the structural stiffness, deformation, and fatigue properties, concerning loading conditions of the force-closed versus the shape-closed stems. In the present study, we sought to fill this void by conducting an extensive structural and fatigue analysis on two cemented femoral stem designs - a collarless force-closed design and a collared shape-closed design. Because excessive pressure is the focus of conservative proximal geometry, we increased the collar width of concentration in the shape-closed design for load distribution to reveal the contrast. By comparing the total deformation, stress, strain, and fatigue safety factor under static and dynamic load, this study attempts to find out which shape design has better biomechanical characteristics of the nail. The following research will provide the basis for the design and selection of future implants by defining the mechanical compromise associated with these two commonly utilized stem types in cemented THA.

II. Methodology

A. Workflow in Brief:

The workflow for the design and validation of an implant stem is illustrated in Fig.1. It starts with CAD modeling, followed by structural analyses under different loading conditions, fatigue analysis, and structural validation, culminating in 3D printing.

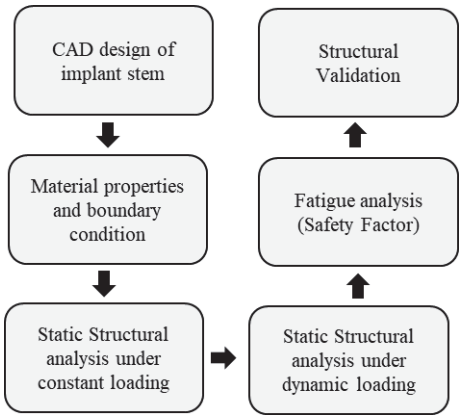

Fig. 1. Methodology flowchart

B. Stem Design:

The stem of implants is traditional in design. Fig. 2 (a) and (b) illustrate a shape-closed and force-closed implant, respectively. One of the main differences between the two designs lies in the presence of a collar and its proximal geometry, which significantly influences the load transfer, friction resistance, subsidence behavior, and distribution of tensile stresses. This design includes a 6 mm thick collar, which is thicker than usual 2mm. The proximal geometry shape is closed and small similar to force force-closed stem.

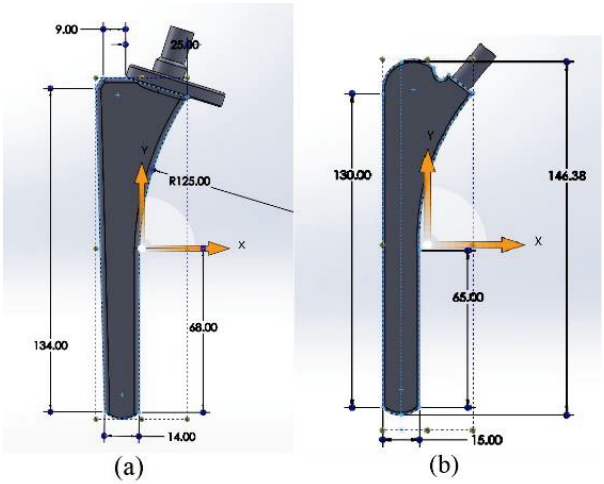

Fig. 2. Shape closed (a) and Force closed (b) hip implant stem

C. Structural Analysis Material Properties

The most common material used to make hip implant stems is Titanium alloy and cobalt-chromium alloy. In this study, titanium alloy is used. In TABLE I, material properties are listed for the titanium alloy.

TABLE I. MATERIAL PROPERTIES

Property	**Value**
Density	4620 kg/m³
Isotropic Secant Coefficient of Thermal Expansion	9.4×10^{-6} °C^{-1}
Young's Modulus	96000 MPa
Poisson's Ratio	0.36
Tensile Yield Strength	930 MPa
Compressive Yield Strength	9.3×10^{8} Pa
Tensile Ultimate Strength	1.07×10^{9} Pa

D. Boundary Conditions

To carry out the static structural analysis, here used a force of 2300.5 N, as a constant force [1]. Fig. 3 (a) and (b) show us the direction of force applied in both shape and force-closed stems. A dynamic loading condition is applied to examine the strength and load-bearing capacity of the implant stem.

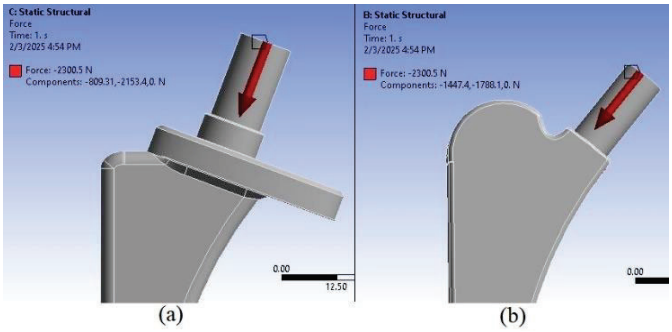

Fig. 3. Force direction on Shape closed (a) and Force closed (b) implant stem.

This dynamic load, expressed as a force versus time percentage curve, shown in Fig. 4, illustrates the variable forces acting on the hip joint during a normal gait cycle [9]. The force curve at the hip joint in walking shows two phases, stance and swing. Because of weight-support, forces on the hip joint are greater in the stance (0–60%) than in the swing (60–100%) phase during walking.

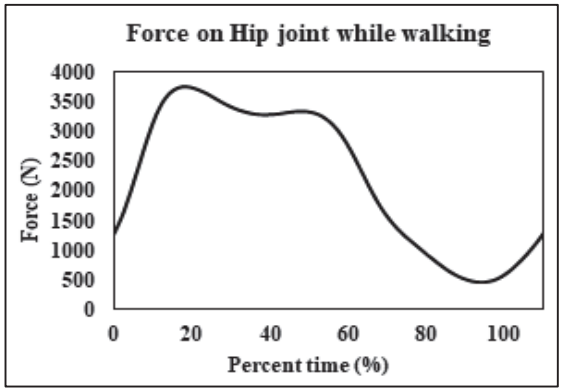

Fig. 4. Dynamic force plot on Hip Joint [9]

E. Fatigue Analysis

The fatigue analysis is carried out to assess the performance of the implants under long-term cyclic loading, which would represent the real-life physiological stresses in daily activity. This analysis provides an estimate of the implant's fatigue resistance as a function of the cyclic loadings and is based upon the S-N (Stress-Number) curve of titanium that describes its fatigue properties [11]. The fatigue safety value characterizes the margin in life by which the implant can withstand cyclic loads without fracture before the design life. A safety factor larger than 1 in fatigue represents survival under cyclic loading and smaller than 1 indicates failure. Maximum safety factor 15 is used to assess the fatigue resistance of the stem designs [10].

III. Results and Discussion

A. Static Structural Analysis Under Constant Loading

A comparative study is carried out on shape-closed and force-closed models to determine the most suitable design for the stem implant. Fig. 5 and Fig. 6 demonstrate the contour plots of von mises stress, deformation and strain for both shape closed and force closed designs. It is observed from TABLE II that, under constant loading of 2300.5 N collared stem exhibited less deformation compared collarless stem.

TABLE II. STRUCTURAL ANALYSIS UNDER CONSTANT LOADING

Design type	Total deformation (mm)	Maximum strain in mm/mm	Equivalent von Mises stress in MPa
Shape closed	6.2654E-03	4.6918E-04	44.662
Force closed	7.7558E-03	1.1998E-03	112.45

a) Equavalent Von Mises Stress: From the von mises stress plot in Fig. 7(a), it is found that the maximum stress in the shape-closed design is 44.662 MPa, while the force-closed design suffered much higher maximum stress of 112.45 MPa. There is almost 2.5-fold stress reduction which indicates that shape-closed stem has superior load-sharing capabilities compared to force-closed stem. There is also decreased likelihood of stress concentrating and developing a fatigue failure in shape-closed stem.

b) Total Deformation: Under constant loading conditions, the total deformation of the femoral stems is shown in Fig. 7(b) for both the shape-closed and force-closed designs. The shape-closed implant demonstrated a total deformation of 6.2654×10^{-3} mm, while the force-closed implant exhibited a significantly higher deformation of 7.7558×10^{-3} mm. The result shows shape-closed stem maintained greater structural rigidity and less deformation under constant loading.

c) Equivalent Strain: The equivalent strain values under constant loading are also compared to support the deformation results. The plots are shown in Fig. 7(c). The shape-closed implant recorded a maximum strain of 2.84×10^{-4}, while the force-closed implant showed a higher strain value of 5.54×10^{-4}. The lower strain in the shape-closed design indicates that it experiences less internal deformation when subjected to external forces.

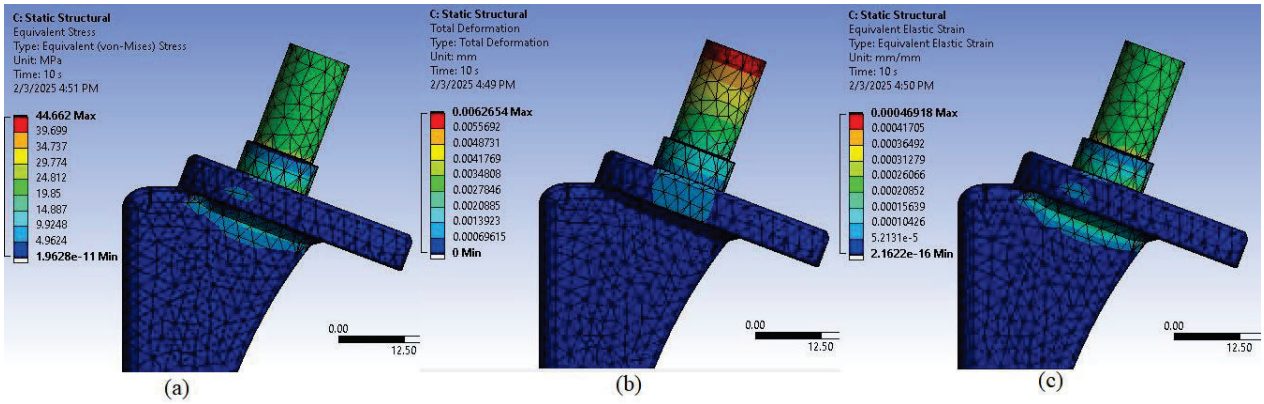

Fig. 5. Contour plots of Equivalent von mises (a), total deformation (b), equivalent strain (c) of the shape closed model

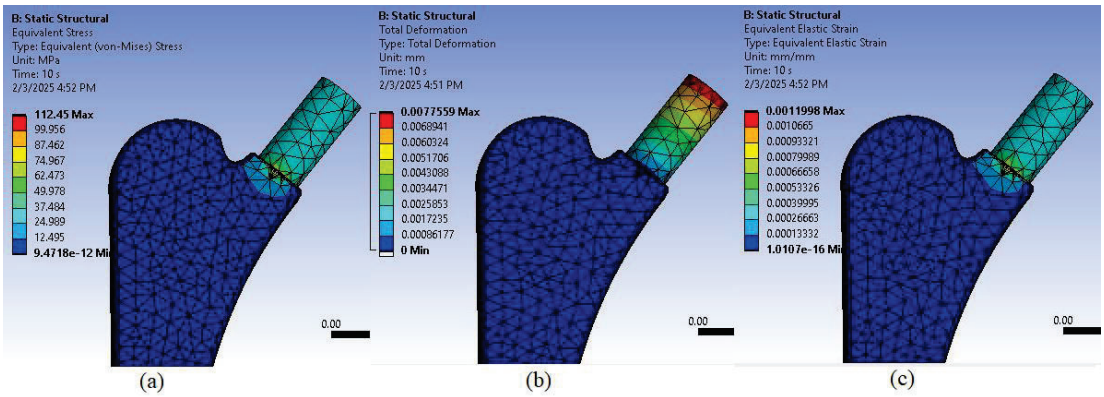

Fig. 6. Contour plots of Equivalent von mises (a), total deformation (b), equivalent strain (c) of force closed model.

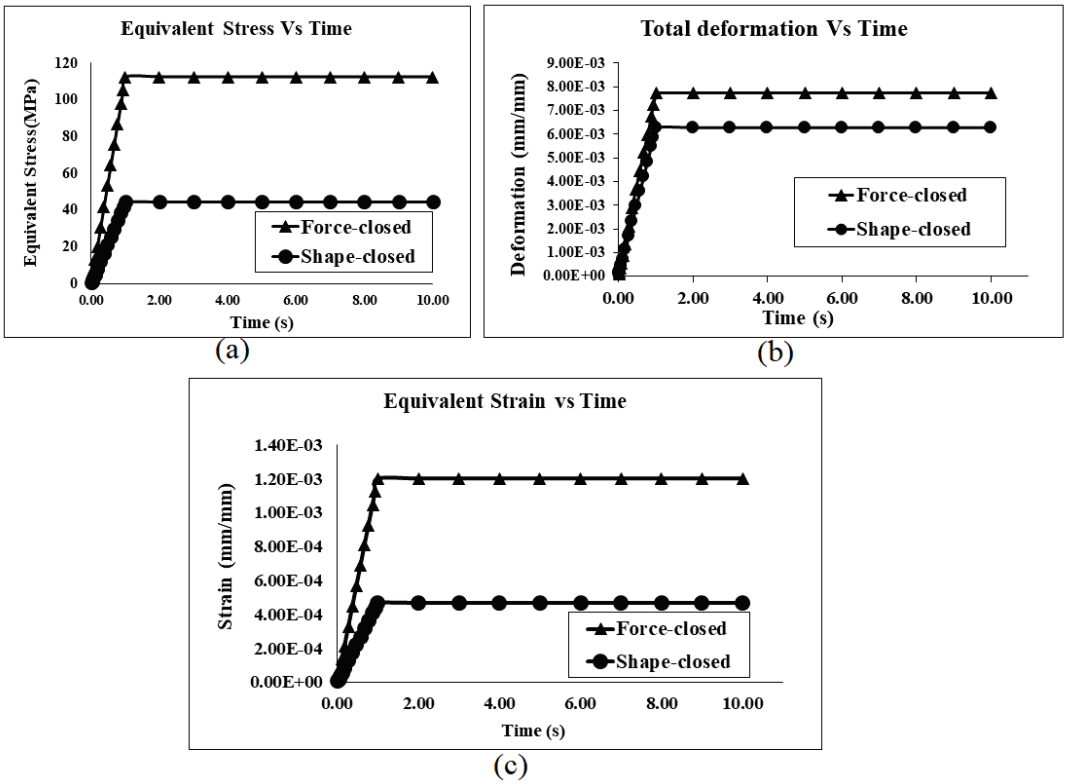

Fig. 7. Structural analysis plots for constant loading condition, Equivalent von Mises (a), total deformation (b), equivalent strain (c)

B. Static Structural Analysis Under Dynamic Loading

Under dynamic loading conditions simulating physiological movement, the shape-closed design continued to outperform the force-closed design. Fig. 8 and Fig. 9 show the contour plots of analysis results for both stem designs. Fig. 10 contains all the relevant plots for von mises stress, deformation, and strain results. TABLE III. outlines the stress, deformation, and strain results.

TABLE III. STRUCTURAL ANALYSIS UNDER DYNAMIC LOADING

Design type	Total deformation in mm	Maximum strain in mm/mm	Equivalent von Mises stress in MPa
Shape closed	3.55E-03	2.8373E-04	27.123
Force closed	1.12E-01	5.5421E-04	53.145

a) Equivalent Von Mises Stress: From Fig. 10(a), the highest von Mises stresses are 27.1 MPa observed in the shape-closed stem, but at the force-closed stem, a much higher stress of 53.1 MPa appeared. This suggests that the shape-closed implant efficiently manages dynamic loads by distributing stresses evenly throughout its structure, thus reducing localized stress concentrations that could lead to fatigue cracks or implant failure over time. Effective stress management under dynamic loading is critical for the longevity and mechanical reliability of hip implants.

b) Total Deformation: Fig. 10(b) illustrates the shape-closed implant exhibited a total deformation of 3.55×10^{-3} mm, remaining stable even under fluctuating forces. Conversely, the force-closed implant demonstrated a considerably higher deformation of 1.12×10^{-1} mm. This shows shape-closed stem is significantly better at maintaining dimensional stability during dynamic

activities, minimizing the risk of micromotion at the bone-implant interface

c) Equivalent Strain: The shape-closed stem showed a maximum strain of 2.84×10^{-4}, compared to 5.54×10^{-4} in the force-closed stem in Fig. 10(c). This suggests that the shape-closed implant efficiently manages dynamic loads by distributing stresses evenly throughout its structure.

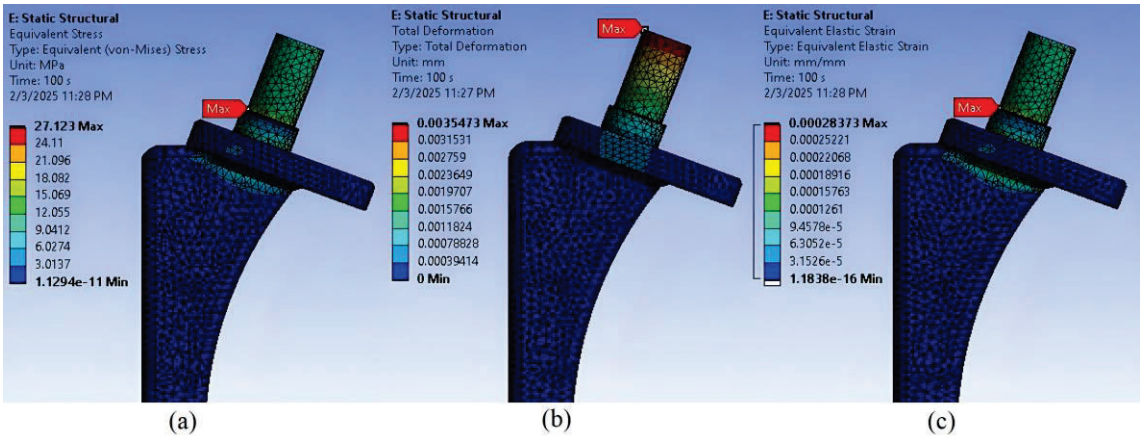

Fig. 8. Contour plots of Equivalent von mises (a), total deformation (b), equivalent strain (c) of force closed model under dynamic conditions.

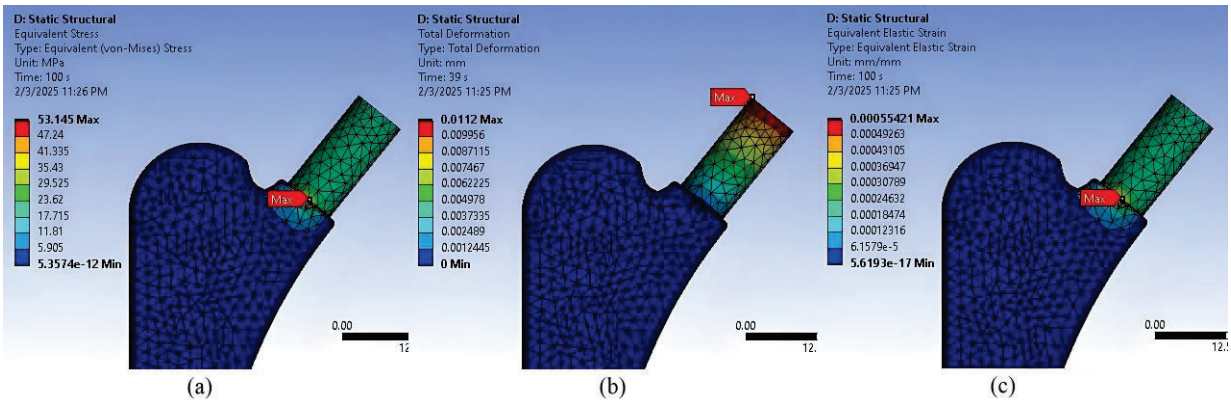

Fig. 9. Contour plots of equivalent von mises (a), total deformation (b), equivalent strain (c) of shape closed model under dynamic conditions

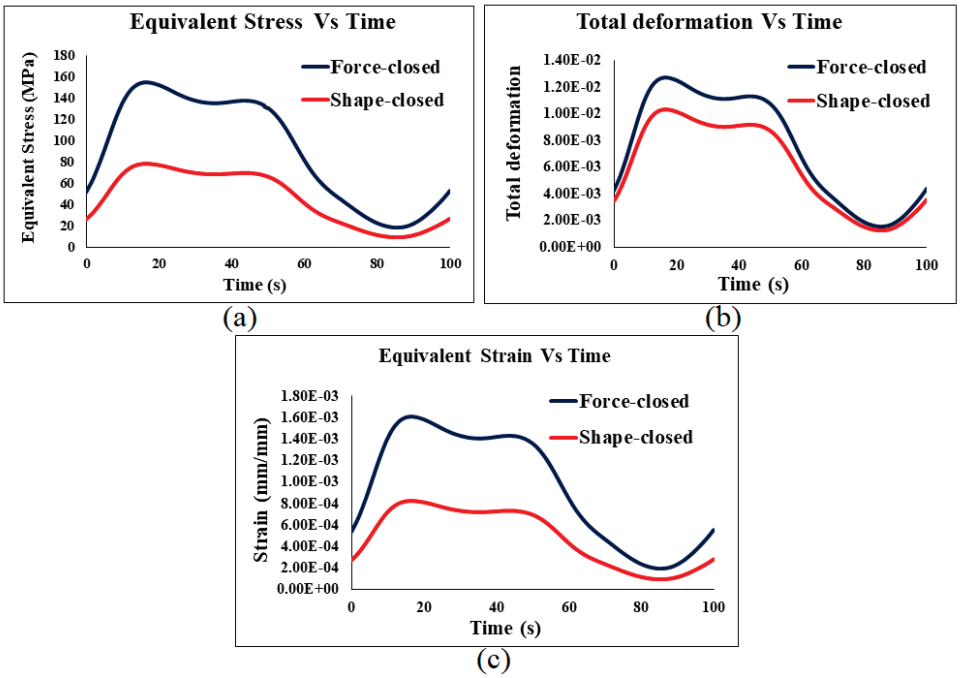

Fig. 10. Structural analysis plots for dynamic loading condition, Equivalent von mises (a), total deformation (b), equivalent strain (c).

C. Fatigue Analysis

The results of the fatigue analysis reveal a significant mechanical advantage of the shape-closed stem over the force-closed stem in both constant and dynamic loading scenarios. As detailed in Table IV, the shape-closed design exhibited a safety factor over twice that of the force-closed design under both constant (8.67 vs. 3.44) and dynamic (14.27 vs. 7.28) loading conditions. These findings indicate that the shape-closed design has superior resistance to cyclic stresses and sustained durability under realistic gait forces.

TABLE IV. SAFETY FACTOR

Design Type	Safety Factor (Constant loading)	Safety Factor (Dynamic loading)
Shape closed	8.6651	14.268
Force closed	3.4415	7.2819

IV. Conclusion

This preliminary study demonstrated that the shape-closed femoral stem, with its refined proximal geometry and the addition of a collar, outperformed the force-closed design under both constant and dynamic loading conditions. The differences were not just qualitative but substantial. Quantitatively, under constant loading, the shape-closed stem carried less than half the von Mises stress of the force-closed design (44.66 MPa vs. 112.45 MPa), deformed less (0.00627 mm vs. 0.00776 mm), and showed lower strain (2.84×10^{-4} vs. 5.54×10^{-4}). Similar trends appeared under dynamic loading, where the shape-closed stem again halved the stress (27.12 MPa vs. 53.15 MPa) and showed dramatically lower deformation (0.00355 mm vs. 0.112 mm). Fatigue analysis reinforced these findings: safety factors for the shape-closed stem were more than twice those of the force-closed stem—8.67 vs. 3.44 in constant loading, and 14.27 vs. 7.28 in dynamic loading. The optimized proximal shape helped reduce internal bone pressure during implantation, improving surgical safety, while the collar enhanced proximal load transfer, reducing stress. These design features contributed to lower von Mises stress, strain, and deformation, as well as significantly higher fatigue safety factors—indicating better structural stability and long-term durability. The structural analysis proves clear mechanical advantages of the shape-closed stem however, this study employed simplified 3D models, one material (Titanium alloy), and simulated only normal gait. Experimental validation were also not accounted for. While the models used in this study captured the essential mechanical behaviors of the implants, future research could benefit from incorporating more complex physiological conditions, a broader range of materials, and detailed modeling of the implant–cement–bone interface. Validating these findings through experimental testing or patient-specific simulations could provide even deeper insight into long-term implant performance. Nonetheless, the results presented here offer strong evidence that a carefully optimized shape-closed design has the potential to improve outcomes in cemented total hip arthroplasty.

***Abstract*— This paper examines the practical use of Digital Twin technology in the reconstruction of multi-story buildings, focusing on the elimination of excessive tilts. The degree of foundation tilt is a critical factor in determining a building's operational suitability. In many cases, however, foundation tilts at different stages of a building's life cycle exceed acceptable or even critical limits. The combination of modern IT solutions, experimental non-destructive testing methods, and Digital Twin concepts makes it possible to assess the current technical condition of a multi-story building, forecast its near-term changes, and manage the process of tilt correction. At the same time, more than 90% of data on changes in a building's technical condition during prolonged alignment works are typically lost or distorted. This study offers a conceptual framework for organizing and protecting data generated during tilt correction using Digital Twins. The application of this IT-based diagnostic approach made it possible to complete the full scope of tilt elimination works across all block sections without interrupting the operation of utilities, elevators, or other technical systems, and without requiring resident evacuation. The key advantages of Digital Twins include the ability to forecast stress–strain changes, provide continuous diagnostic information, optimize processes, analyze and visualize real-time sensor data distributed throughout the building, simulate alternative tilt-correction scenarios, and support efficient resource management.**

Keywords*— modern IT solutions, digital twins, cyber-physical systems, excessive foundation tilts, reconstruction

I. INTRODUCTION

The use of digital technologies across many industries is undergoing rapid transformation, especially with the advent of Industry 4.0. Yet the domestic construction sector has been slow to adopt and apply these technologies. International experience shows that digital technologies in construction improve productivity, enhance quality and efficiency, and strengthen collaboration among stakeholders, thereby increasing project success [1]. Notable examples include Building Information Modeling (BIM), Digital Twins (DT), Distributed Ledger Technology (DLT) or Blockchain, 3D printing, the Internet of Things (IoT), Artificial Intelligence (AI), and Augmented or Virtual Reality (AR/VR) [2]. Within the framework of Construction 4.0, efforts are being made to introduce these advanced tools and apply them across different stages of a building's life cycle. In Ukraine, however, the practice of implementing IT systems for real-time diagnostics of building conditions remains rare, with only isolated cases to date. The development of such monitoring systems is shaped by several key factors: technical – identifying the physical and mechanical parameters on which the measurement system relies; technological – designing methods and procedures for manufacturing components, installing the system, and ensuring reliable operation; and economic – optimizing the cost parameters of the system [3]. Acceptable values for certain technical condition parameters of buildings and structures, such as foundation tilt (Fig. 1), are defined by regulatory documents [4, 5].

Uncertainty in the "foundation–multi-story building" system can result from flooding, seismic activity, emergency water supply failures, man-made vibrations (e.g., from transport or operating equipment), or changes in load due to increased building density, among other factors. Assessing the stress–strain state of the "soil–foundation" system during tilt correction requires monitoring multiple physical parameters. This, in turn, demands the use of numerous sensors and various primary measuring devices with different designs and operating principles. Examples include strain gauges, magnetoelastic and magnetostrictive devices for measuring forces and stresses; inductive and electromagnetic devices for measuring linear and angular displacements; and liquid-based devices for measuring relative settlements and foundation deformations.

The use of modern information technologies for diagnosing the current technical state of multi-story buildings during tilt elimination makes it possible to save both time and money, while also broadening knowledge of building components, foundations, and soil conditions, all while maintaining acceptable safety levels. A Digital Twin is based on real-time monitoring and analysis of the key parameters of

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

the soil–foundation system, which allows revisions to the project at any stage of work [16, 17]. A universal DT must also include a module for continuous calculation of the stress–strain state of the soil and superstructure during the tilt elimination process, as well as a module for generating current management commands [16]. Technological settlements and tilts of the building are predicted using modern numerical methods, taking into account excavation specifics, drilling of wells, and other factors.

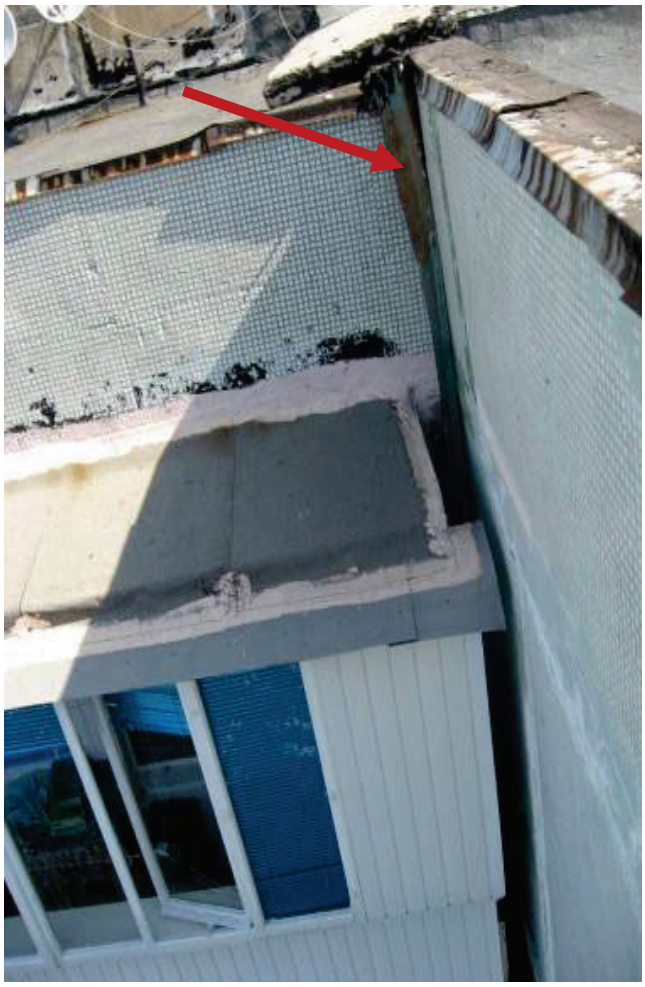

Fig. 1. Closure of the expansion joint and leaning of block-sections No. 3, 1 of residential buildings No. 23, 25 at Preobrazhenska Street in the city of Zaporizhzhia.

To create geomechanical and structural models of the "underworked soil mass (base) – tilted foundation" system, the general patterns of soil deformation, and in particular the contours of cylindrical wells, were studied. For effective decision-making and risk reduction, comprehensive DT-based information about the current technical state of the building is essential [18]. Such information can be obtained by performing a series of residual capacity checks for the main structural elements of the soil–foundation–superstructure system using real-time DT results. Calculations in LIRA CAD [14, 19] are based on a finite element spatial model of the building (Fig. 2).

The finite element method forms the theoretical basis of LIRA CAD. The implemented version of finite element method uses the principle of possible displacements:

$$a(u, v)=(f, v) \tag{1}$$

where u is the exact solution to be found, v is any possible displacement, $a(u, v)$ and (f, v) represent the possible actions of external and internal forces. The structure's domain is divided into finite elements Ω_r, and nodes with associated degrees of freedom L_i (displacements and rotations) are assigned. The approximate solution U_h must satisfy the main kinematic conditions and is expressed as a linear combination of the basic functions.

Let K be the stiffness matrix, P – the load vector and X – the vector of unknowns.

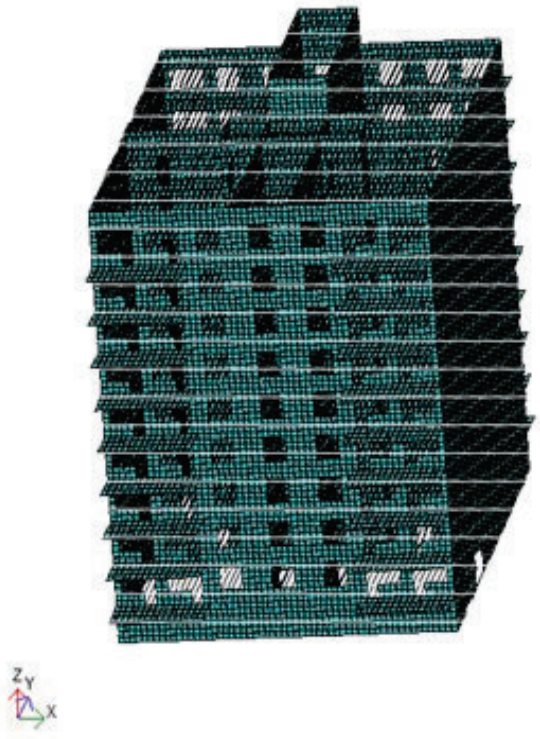

Fig. 2. Calculation model of a building that has undergone tilting.

Then can be written in matrix form as:

$$KX=P \tag{2}$$

Thus, finite element method reduces the problem to solving a system of linear algebraic equations (2). A key advantage is that the stiffness matrix K and load vector P are obtained by summing contributions from individual finite elements.

The Finite Element Library includes elements modeling the behavior of different structures: bar elements; quadrilateral and triangular elements for planar problems (e.g., slabs, shells); spatial elements such as tetrahedra, parallelepipeds, and trihedral prisms. It also includes special elements modeling finite stiffness connections, elastic compliance between nodes, and user-defined stiffness matrices. All elements in the Finite Element Library are theoretically validated, with established energy and displacement error estimates.

Some Ukrainian researchers are actively developing theoretical and methodological foundations and tools for creating and applying IT solutions in construction, assessing technical condition of multi-story buildings, and designing

and implementing information-analytical decision-support systems based on LIRA-CAD [6–12].

II. Digital Twin Technology in Eliminating Excessive Tilts of Multi-Story Buildings

If there is a fully integrated, automatic, two-way data exchange in real time between a physical object and its digital model, this is called a Digital Twin [13]. In such cases, the digital model can function as a controlling counterpart to the physical object. Other objects, physical or digital, may also influence the model.

Changes in the physical object's technical state lead to immediate updates in the digital model, and the reverse can also occur (see Fig. 3, adapted from [13]).

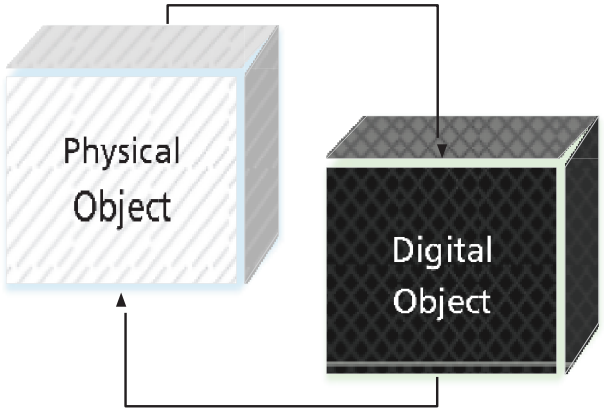

Fig. 3. Data Flow in a Digital Twin [13].

The application of Digital Twin technology for eliminating excessive tilts in multi-story buildings, and the components of this approach, are described below. A key element is the automated information-measuring system Monitoring, designed to measure tilt directions and angles of buildings and their elements in real time, ensuring safe correction of excessive tilts.

This system is based on inductive transducers and supports remote data acquisition, processing, and transmission from sensitive elements. Monitoring the stress–strain state of a building during tilt correction is achieved through an algorithm consisting of sequentially linked tasks, grouped into blocks: science and research, measurement and information, admission and control, calculation and analysis, and design and technology. The technical components of the Monitoring system are shown in Fig. 4.

Data are transmitted over the Internet (IoT) to cloud or PC, with subsequent processing. The system operates automatically with programmable activation intervals, powered by ~220 V supply. An uninterruptible power supply ensures 1000 hours in standby mode or 48 hours in measurement mode. Every 12 hours, the battery charge of the system is checked. After polling sensors (99 sensors in 12 seconds), the system enters power-saving mode. During development, an original inductance meter was created and integrated into the sensors.

Its sensitivity is 0.5 μH, with an error of only 0.2% across the working range. The displacement accuracy is 0.001 mm, while tilt error is 0.05%. The data collection unit provides multiple functions: power supply (from grid or battery), UPS charging, powering sensors via communication lines, data collection from sensors, data transmission and control, saving settings in non-volatile memory, entering power-saving mode between cycles, and connecting to communication lines via DB9 connector.

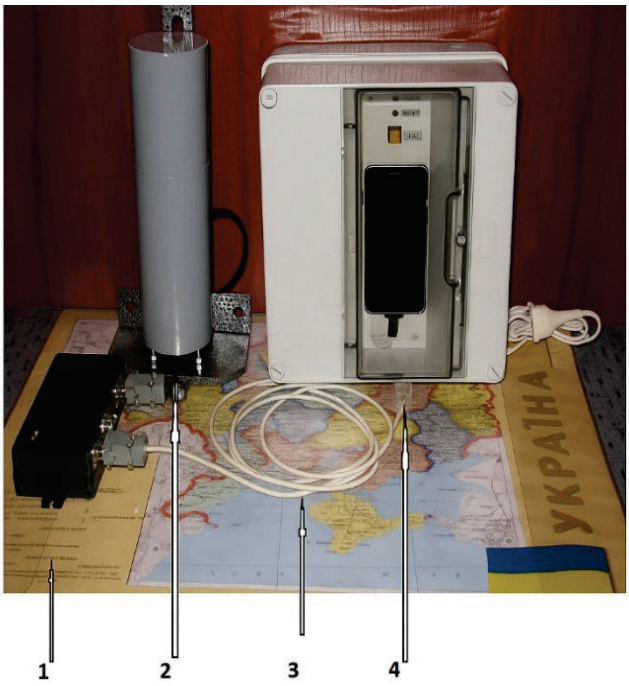

Fig. 4. Technical components of the automated information-measuring system Monitoring: 1 – inductance meter; 2 – angular deformation sensor; 3 – communication lines; 4 – data collection and transmission unit (IoT).

A schematic of the Monitoring system installed in a multi-story building is shown in Fig. 5 [15, 16].

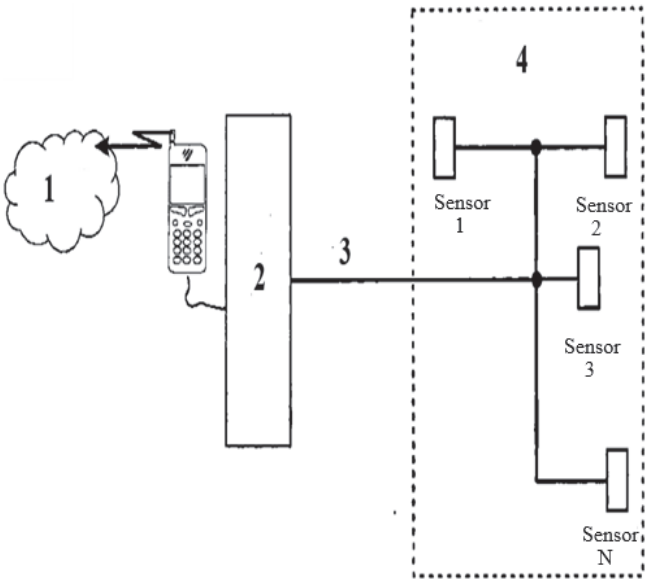

Fig. 5. Schematic of the Monitoring system in a multi-story building: 1 – Internet; 2 – data collection unit; 3 – communication line; 4 – measurement object.

The external appearance of a universal inductive sensor with an inductance meter, installed in the basement of a tilted residential building in Zaporizhzhia, is presented in Fig. 6.

The collection of information from precision inclinometric sensors (measuring tilt angles of structural elements)

distributed throughout the building is facilitated by IoT (No. 4 in Fig. 4 and No. 1 in Fig. 5).

Fig. 6. The appearance of the universal inductive device sensor installed on a wall in the basement of the building.

Current experimental measurements of the stress–strain state and technical condition of the building are promptly processed and provided to decision-makers to determine whether alignment should continue or be suspended. Processing of these online results by the monitoring system initiates the following management actions: (1) sequential adjustment of the digital model according to the calculated stress–strain parameters of the tilted building using the LIRA-CAD software suite [14, 19]; (2) comprehensive analysis of results to identify structural elements in critical states and, if needed, reinforcement measures [17]; (3) selection of technological methods for settlement adjustment based on the calculated stress–strain diagram; (4) implementation of corrective measures when discrepancies arise between actual and projected parameters such as settlement or tilt.

For this reason, straightening projects must include engineering measures to ensure feedback (Fig. 3). This feedback loop ensures consistency between predicted and observed deformations under conditions of uncertainty and potential ground failures, and helps identify soil zones requiring additional intervention. Such interventions may include correcting settlements under strip foundations by drilling supplementary boreholes of various diameters, moistening soil beneath foundations, and other methods. The ultimate goal is to securely stabilize the building in its new position, ensuring reliable performance during alignment without interrupting utilities, technical systems (elevators, etc.), or requiring resident evacuation.

Initial and boundary conditions are updated based on current inclinometer readings across the building, taking into account its actual technical state at the time of calculation. These measures increase the reliability of decision-support systems and the accuracy of managerial commands issued by project executives, while also allowing identification of localized soil areas requiring targeted management actions, such as settlement correction beneath strip foundations.

The DT uses the following instruments: universal inductive tilt sensors (Fig. 6) and crack-width sensors (accuracy: 0.001 m), operating within –30º…+70ºC and protected against dust and moisture (IP56); an inductance meter for recording; a mobile-phone-based IoT unit for data collection and transmission; and the Pendulum software package [15].

To improve measurement accuracy, the device incorporates several techniques: warming-up before data collection (about 75% of total measurement time), averaging nine consecutive readings, and normalization against a reference coil. Normalization is used because inductance of ferromagnetic-core coils strongly depends on current magnitude due to nonlinearity of the magnetization curve. The reference coil also compensates for temperature effects on coil properties and circuit elements. For robust compensation, the reference coil must be of the same type as those being measured. The meter transmits both normalized and raw measurement values to the collection unit, enabling verification of normalization accuracy.

During tilt correction, discrepancies often arise between actual and predicted values of settlement or tilt. Therefore, additional engineering measures such as real-time monitoring and technological settlement-control methods must be included in design projects. This ensures consistency between predicted and actual deformations of the “underworked soil–tilted strip foundation” system throughout tilt elimination.

III. Results

The development of horizontal displacements along the x and y axes during tilt elimination is presented in Fig. 7, in a format convenient for decision-makers.

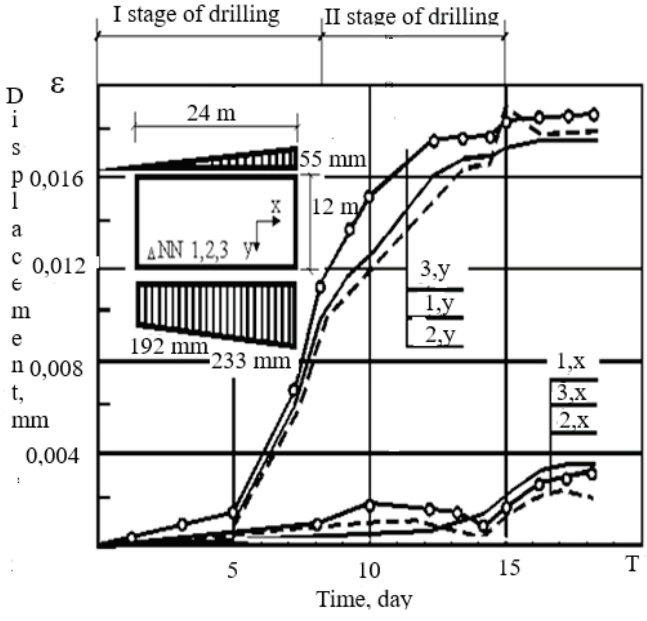

Fig. 7. Development of horizontal displacements along the x and y axes during elimination of excessive tilt in a multi-story building. Sensors No. 1, 2, 3 were installed in the basement, second floor, and roof, respectively.

Five phases of tilt changes in the block sections of the building were observed: (1) minor settlements during the first

stage of drilling; (2) active progressive deformations during the second stage of drilling and immediately after completion; (3) stabilization of settlements after drilling works; (4) active progressive deformations during adjustment of technological settlements by moistening the soil around wells; (5) stabilization of deformation processes.

IV. Conclusions

Modern IT solutions and Blockchain technology for eliminating excessive foundation tilts in multi-story buildings were examined. The integration of IT systems with non-destructive testing methods and Digital Twin technology allows real-time assessment of building condition, forecasting of near-term changes, and management of tilt correction [17]. However, over 90% of condition-change data generated during prolonged alignment is typically lost or distorted.

The graphs (Fig. 7) illustrate the development of horizontal displacements along the x and y axes throughout tilt correction. Five distinct phases of tilt development were observed: (1) minor settlements during the first drilling stage; (2) active deformations during and immediately after the second stage; (3) stabilization after drilling; (4) active deformations during adjustment of technological settlements by soil moistening; (5) stabilization of deformation processes. This IT-based approach made it possible to complete all tilt elimination works across all block sections without halting utilities, technical equipment (elevators, etc.), or requiring resident evacuation.

The key advantages of Digital Twins include the ability to analyze and visualize real-time sensor data distributed throughout the building, provide continuous diagnostic information, optimize processes, simulate alternative tilt-correction scenarios, forecast stress–strain changes, and support efficient resource management. These capabilities ensure more effective and economically efficient management across all stages of a building's lifecycle [18].

***Abstract*— The work is dedicated to the further development of the theoretical foundations of a special class of induction-synchronous electromechanical converters (ISEMC) with an enhanced design. Using numerical calculation methods with the application of circuit-field modeling, a study of steady-state and transient electromagnetic and mechanical processes in an ISEMC has been conducted. Based on the results of circuit-field modeling, the regulation properties have been determined for the first time, and a family of regulation and mechanical characteristics, as well as the operating characteristic regarding the dependence of the armature current on the mechanical power, have been obtained for different values of the applied supply voltage under conditions of combined and separate operation of the induction motor (IM) and synchronous generator (SG) parts of the ISEMC operating in the motor mode. For the first time, the stability criteria of induction-synchronous electromechanical converters for the motor operating mode have been determined.**

Keywords*— induction-synchronous electromechanical converters, regulation properties, characteristic, stability criteria, field current, armature current

I. Introduction

In the context of the active development of power engineering, production automation, and the implementation of energy-efficient technologies, the need for electromechanical systems with high levels of reliability, energy efficiency, and compactness is increasing [1]. This is particularly relevant for AC electric drives operating at reduced rotational speeds, where the use of gearboxes is undesirable or impossible due to limitations in dimension, noise, or maintenance [2]-[4]. In such cases, slow-speed synchronous motors, capable of developing nominal torque at low rotational speeds [5], become the optimal solution.

Electric machines with combined windings are of additional interest, as its provide expanded functionality, as follows: operation in various modes (supply network/inverter, power supply from two independent sources, etc.); increased fault tolerance and reliability; and flexibility in torque and speed control. The implementation of electric machines with combined windings also allows for increased efficiency and reduced electromagnetic torque ripple [6], which is particularly important for precise and dynamically complex systems such as CNC machine tools, conveyors, robotics, and direct drive systems in power engineering and transport [7]-[9]. Thus, the development of slow-speed synchronous motors with combined windings represents an important and promising direction in the field of electrical machines, contributing to the creation of modern, highly efficient, and technologically flexible electromechanical systems.

II. Analysis Of Last Researches

In modern AC electric drive systems, various types of electromechanical converters (EMC) can be used, such as: asynchronous motors with a squirrel-cage rotor and a wound rotor, synchronous motors with slip rings, contactless synchronous machines (CSM) with electromagnetic or permanent magnet excitation, and others. The advantages and disadvantages of these EMCs, as well as their regulated characteristics, are well-known. Along with the most common classes of EMC, cascade EMC combined in a single magnetic core with combined armature windings (CAW) are being developed [10]-[12]. The fundamental idea of creating combined EMC has been known for a long time and has been used in the creation of a variety of their designs [10]-[13]. Combined EMC were not considered from the perspective of the general theory of EMC, and the further development of their theory was classified as belonging to the class of special EMC [10]. Until recently, this class of EMC did not have prospects for further development due to existing drawbacks in their design: the presence of a rectifier in the rotor, which leads to a significant increase in weight and dimension characteristics, complexity in manufacturing technology and maintenance; increased inertia of regulation due to the increased electromagnetic time constant of the exciter's field winding [10]. In papers [10]-[13], the authors proposed a new class of induction-synchronous EMC (ISEMC), which represents a further stage in the development and improvement of the design of cascade low-speed combined EMC, that combine the properties of an induction motor (IM) and a synchronous generator (SG) [12]. The design peculiarity consists in the following: the stator winding of the first EMC is a three-phase $2p_1$-pole winding, and the stator winding of the second EMC is a single-phase $2p_2$-pole field winding. The three-phase $2p_1$-pole winding and the single-phase $2p_2$-pole winding are electrically combined with each other and form a single conductive system on the stator (armature) side of the ISEMC Each phase of the armature winding consists of two parallel branches of coil groups, the terminals of which are connected to two separate neutral points ("Y-connection"). The terminals of the cathode and anode valve groups of a controlled (or uncontrolled) rectifier are connected to these neutral points to provide the combined armature winding with field current [14], [15]. Using the developed universal method for determining the optimal winding factor of EMC, the author [16] proposed, for combined rotor windings, to exclude the

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

sections of those coils, whose currents create oppositely directed MMF vectors. And those rotor core slots in which these sections were located should not be punched [12]. In this case, the design of the rotor winding is significantly simplified and will consist of electrically unconnected short-circuited coils, the number of which is determined by the sum of the number of poles of the two combined EMCs [12]. Thus, the presence of electrically combined excitation and armature windings in the common conductive system on the stationary armature side of the ISEMC, electrically unconnected short-circuited coils of the rotor winding, as well as the absence of permanent magnets, a brush mechanism, and a damper winding, highlight distinct positive features of the ISEMC's design compared to known designs of contact and contactless synchronous EMCs.

To research the steady-state and transient electromagnetic and mechanical processes of this ISEMC design, the author in [10], [12] developed an adapted dynamic 2D circuit-field model of the transient interconnected electromagnetic and electromechanical processes of the ISEMC. This model allows for the consideration of the parameters of the end-winding parts in transient operating modes through its circuit implementation, the nonlinearity of the magnetic and electrophysical properties of the active materials, and the surface and edge effects of the end arias of its active part. Also, in [10], [13], methods were developed and a methodology was presented for determining the active and inductive resistances of the end-winding parts of the ISEM windings, taking into account the effect of edge effects, which made it possible to obtain a qualitative transition from a 3D to a 2D circuit-field model of the ISEMC.

In [12]-[15], the author used numerical modeling methods to research the electromagnetic and mechanical processes in the idle mode with the combined interaction of the induction and synchronous parts within the single active part of the ISEMC. The presence of self-synchronizing properties for the ISEMC was demonstrated, whereby asynchronous starting is ensured, followed by the pulling of its rotor into synchronism in the idle mode without excitation, and the conditions for their occurrence are explained. The relationships between the idle current and the excitation current, which determine the operation of the synchronous part of the ISEMC in underexcited, normally excited, and overexcited modes, were established. It has been proven, that in underexcited and normally excited modes, its synchronous part operates as a reactive power compensator, and in the overexcited mode, it operates as a generator.

Thus, the preliminary results obtained from the study of electromagnetic and mechanical processes in the enhanced ISEC design require further research of electromagnetic and mechanical processes, determination of its regulated properties and characteristics, as well as the formulation of criteria for the stable operation of the ISEMC in motor mode.

III. Formulation Of The Work Purpose

The aim of the work is to research the electromagnetic and mechanical processes in the ISEMC, to determine its regulated properties and characteristics, as well as to formulate criteria for the stable operation of the ISEMC in motor mode.

IV. Expounding The Main Material

The study of the electromagnetic and mechanical processes of the ISEMC was carried out for a manufactured experimental sample of the ISEMC (based on the MTF-111-6 crane motor) with a combined $2p_1$=4 and $2p_2$=8 armature winding (cascade rotation speed n=500 rpm) with a number of rotor phase coils n_2=6, a supply frequency of the armature winding f_1=50 Hz, at U_{phase}=54V, U_{phase} =74V, U_{phase}=92V, U_{phase}=108V (nominal phase voltage U_{rated} =74V). The electrical circuit of the model implementation of the armature and rotor windings of the ISEMC is fully described and presented in [17]. The schematic-geometric view of the 2D circuit-field model of the ISEMC is shown in Figure 1 (the connection of the end-winding and slot parts of the armature and rotor windings is not shown).

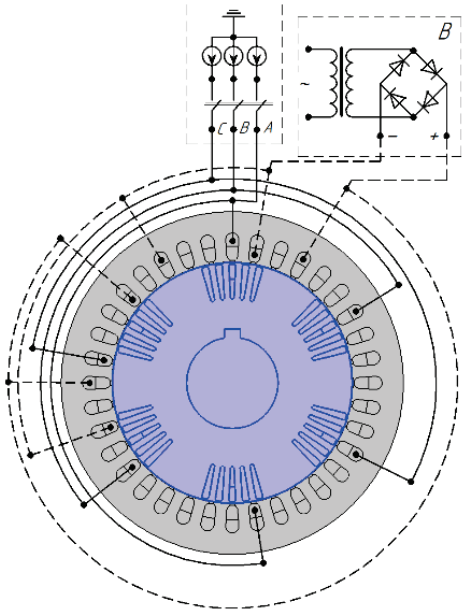

Fig. 1. Schematic-geometric view of the 2D circuit-field model of the ISEMC

In this case, the 2D field part of the mathematical model describes the transient electromagnetic processes in the calculation domain of the ISEMC using a system of nonlinear partial differential equations [17]-[19]:

$$\sigma_j \frac{\partial \mathbf{A}_j}{\partial t} + \nabla \times \left[\left(\mu_0 \mu_j (B) \right)^{-1} \nabla \times \mathbf{A}_j \right] - \ldots \\ \ldots - \sigma_j \mathbf{v} \times (\nabla \times \mathbf{A}) = \mathbf{J}_{ej} \quad (1)$$

where $\boldsymbol{A}$ is magnetic vector potential; $\boldsymbol{B}$ is magnetic flux density; μ, σ is accordingly relative magnetic permeability and electrical conductivity (for each calculation domain, it is specified separately according to the magnetic and electrophysical properties of the materials); $\boldsymbol{J}_e$ is current density of external sources; index j is corresponds to the subdomains of the geometric calculation area; $\boldsymbol{v}$ is velocity vector of the rotor's calculation domain relative to the stator's coordinate system, which is determined by the angular velocity of the rotor ω_m and the radius vector of a point in the rotor's calculation domain $\boldsymbol{r}$ ($\boldsymbol{v}$= $\omega_m \times \boldsymbol{r}$);

In accordance with [17], [18], the system of equations (1) is supplemented by the Coulomb gauge condition. Homogeneous boundary conditions are set on the external

boundaries of the 2D domain of the ISEMC's geometric model [19]. Equation (1) is supplemented by the coupling equations of the magnetic field and the electric circuit when phases A, B, C of the armature winding are supplied from the network, and also when supplied by the rectified current id from the excitation source, which flows through the neutral points "0+" and "0-":

$$\begin{cases} u_{m,n} \pm u_d = \dfrac{d\Psi_{m,n}}{dt} + L_{fr,n} \cdot \dfrac{d}{dt}\left(i_{m,n} \pm i_{f,n}\right) + \ldots \\ \ldots + \left(r_{fr,n} + r_{s,n}\right) \cdot \left(i_{m,n} \pm i_{f,n}\right), \\ \Psi_{m,n} = 2 \cdot \dfrac{n_w \cdot l_z}{S_{n.eff}} \int\limits_{S_a} A_{i,j} ds; i_{f,n} = \dfrac{i_d}{3}; \\ J_e = \dfrac{n_w \cdot \left(i_{m,n} \pm i_{f,n}\right)}{S_{n.eff.}}, \end{cases} \quad (2)$$

where m=A,B,C and n=1,2 are the phase index and parallel branch (coil group) of the armature winding phase; $u_{m,n}$ is voltage applied to the armature winding of the corresponding phase; $\psi_{m,n}$, $i_{m,n}$ are magnetic flux linkage and currents of parallel branches of phase coil groups n of the corresponding phase m of the armature winding; $L_{fr,n}$, $r_{fr,n}$, $r_{s,n}$ are respectively, the inductance of the frontal part and the resistances of the frontal and slots parts of the parallel armature winding branch; u_d, i_d, are rectified voltage and current of the excitation system; $i_{f,n}$ are the field currents flowing in the corresponding parallel branch n of phase m of the armature winding (the "±" is sign corresponds to the direction of the field current flow); n_w is number of turns of the armature winding; $S_{n.eff}$ – cross section of an effective conductor; S_a – total cross-sectional area of all turns of the parallel branch of the coil group.

The mathematical model (1)-(2) is also supplemented by the coupling equations of the magnetic field and the electric circuit of the rotor winding, which consists of r electrically unconnected coils:

$$0 = \frac{d\Psi_{m2,r}}{dt} + L_{fr,r} \cdot \frac{di_{m2,r}}{dt} + \left(r_{fr,r} + r_{s,r}\right) \cdot i_{m2,r}, \quad (3)$$

where $\psi_{m2,r}$, $i_{m2,r}$ are magnetic flux linkage and currents of the corresponding short-circuited rotor winding coil; $L_{fr,r}$, $r_{s,r}$, $r_{fr,r}$, are respectively, the inductance of the frontal parts and the resistances of the slot and frontal parts of the short-circuited rotor winding coils.

To investigate the ISEMC in idle and loaded modes, the system of equations of the mathematical model (1)-(3) is supplemented by the rotor's angular velocity equation and the electromagnetic torque equation [20]:

$$\begin{cases} \dfrac{d\omega_m}{dt} = \dfrac{M_e - M_c}{J}; \dfrac{d\phi}{dt} = \omega_m; \\ M_e = \dfrac{1}{R_o - R_i} \cdot \dfrac{l_z}{\mu_0} \int\limits_{S_{ag}} B_r B_\varphi \, dS_{ag}, \end{cases}, \quad (4)$$

where M_e is electromagnetic torque; M_c is load torque; J is rotor inertia moment; ω_m is rotor angular velocity; φ is rotor position angle; R_o is outer radius of the air gap; R_i is internal radius of the air gap; S_{ag} is cross-sectional area of the air gap.

The circuit implementation of the armature winding and the rotor winding, together with the equations of the mathematical model of the electromagnetic field, was carried out using the Comsol Multiphysics software with the use of a multiphysics structure combining the "Rotating Machinery, Magnetic" and "Electrical Circuit" interfaces. The connection and coordination of the parameters of the slot parts of the armature and rotor windings, which are elements of both the field model and the elements of the electrical circuit, is performed using "External I vs. U" terminals.

Considering the results of previous research by the authors [17], a U-shaped regulation characteristic of the ISEMC in idle operation was constructed based on the results of numerical calculation using finite element modeling for cases when the phase voltage is less than the nominal value (U_{phase}< U_{rated}) as well as ($U_{phase} \geqslant U_{rated}$) (Fig. 2).

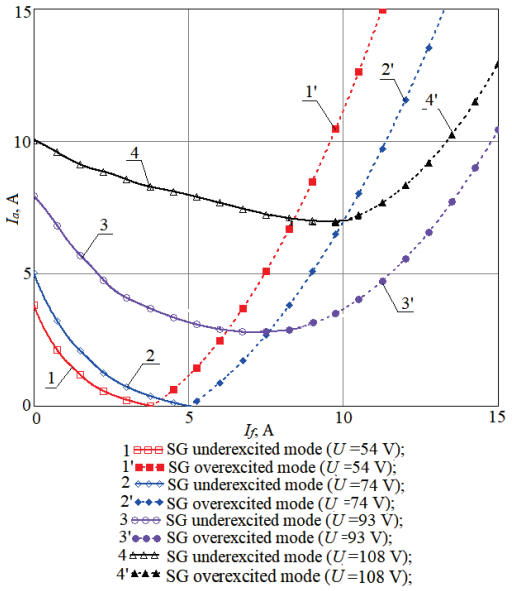

Fig. 2. General regulation characteristic at different values of the applied voltage to the armature winding of the experimental ISEMC in idle operation mode

The point of conditional symmetry of the U-shaped regulation characteristic of the ISEMC in idle operation will be determined by the condition of equality between the idle current I_{idle} of the IM part at the corresponding voltage U_{phase} and the field current I_f of the SG part of the ISEMC, that is I_f = I_{idle}. In this case, the SG part of the ISEMC operates in the normally excited mode. The left and right branches of the U-shaped regulation characteristic of the ISEMC will correspond to the underexcited and overexcited modes of the SG part of the ISEMC, respectively (fig. 2).

When U_{phase}<U_{rated}, the U-shaped regulation characteristic shifts to the left relative to the U-shaped regulation characteristic when U_{phase}=U_{rated} (U_{rated} =74V) (fig. 2). For this case, the normally excited mode of the SG part of the ISEMC will be achieved at a smaller value of I_f (I_f < $I_{f.rated}$), which will be equal to I_{idle} at the corresponding voltage U_{phase} (curve 1, fig. 2). In the overexcited mode of the SG, the armature current is generated by the SG part of the ISEMC and will already have active and reactive components, since E_{SG} > U_{phase} (curve 1', fig. 2).

When U_{phase} < U_{rated}, the U-shaped regulation characteristic shifts to the left relative to the U-shaped regulation characteristic when U_{phase} = U_{rated} (U_{rated} =74V)

(fig. 2). For this case, the normally excited mode of the SG part of the ISEMC will be achieved at a smaller value of I_f ($I_f < I_{f.rated}$), which will be equal to I_{idle} at the corresponding voltage U_{phase} (curve 1, fig. 2). In the overexcited mode of the SG, the armature current is generated by the SG part of the ISEMC and will already have active and reactive components, since $E_{SG} > U_{phase}$ (curve 1', fig. 2).

When $U_{phase} > U_{rated}$, the U-shaped regulation characteristic shifts to the right relative to the U-shaped regulation characteristic when $U_{phase} = U_{rated}$, and the normally excited mode of the SG part of the ISEMC will for $I_f > I_{f.rated}$. However, in this case, the EMF of SG part of the ISEMC will always be $E_{SG} < U_{phase}$. In this case, the reactive power of the IM part of the ISEMC will not be fully compensated, and therefore neither will the reactive component of the current I_{idle}.

The smallest value of the idle current I_{idle} for the U-shaped regulation characteristics when $U_{phase} > U_{rated}$ will be determined by the points of their intersection with the right branch of the U-shaped regulation characteristic at the nominal voltage value $U_{phase} = U_{rated}$ (curve 2', fig. 2).

With the appearance and subsequent increase of the load M_c, provided there is complete compensation of the reactive power of the IM part of the ISEMC (when $U_{phase} \leqslant U_{rated}$), meaning when the SG part of the ISEMC operates in the normally excited mode, the current I_a consumed from the supply network will only have an active component $I_{a.}|_{active}$. In this case, due to the combined effect of the electromagnetic torque from the IM part and the reactive torque of the SG part of the ISEMC, the synchronous rotational speed of the rotor will be maintained as long as the value of the armature current is less than or equal to the field current ($I_a \leqslant I_f$). In this case, the armature current I_a will always be greater than I_{idle} ($I_a > I_{idle}$), and the U-shaped regulation characteristic itself will shift upwards for all values of U_{phase}.

When $I_a > I_f$, the ISEMC rotor loses synchronism and begins to rotate with slip. With an increase in I_f, when the condition $I_a \leqslant I_f$ is met again, the ISEMC rotor is automatically pulled back into synchronism.

Thus, two stability criteria for the ISEMC can be defined. The first stability criterion for the ISEMC is that to ensure the operation of its SG part in underexcited and normally excited modes, the condition $I_f \leqslant I_{idle}$ must be satisfied, that is:

$$k\big|_{sc}^{1} = \left\{ I_f \leq I_{idle}\big|^{IM} \right\}. \tag{5}$$

This condition is a limitation on the field current I_f.

If $I_f > I_{idle}$, the SG part of the ISEMC transitions to the overexcited mode, which leads to the predominant effect of the SG part over the IM part of the ISEMC. This causes oscillatory processes in the resulting electromagnetic torque, as well as in the rotational speed of the ISEMC rotor, which leads to it losing synchronism followed by "tipping" [17].

The second stability criterion for the ISEMC is that to ensure the synchronization of the rotor under load, that is, to ensure the nominal synchronous speed of the ISEMC rotor, the condition $I_a \leqslant I_f$ must be satisfied:

$$k\big|_{sc}^{2} = \left\{ I_a \leq I_f \right\}. \tag{6}$$

When $I_a > I_f$, the ISEMC lacks the reactive synchronizing torque, which created by the SG part of the ISEMC to maintain the synchronization. This leads to the desynchronization of the rotor, the appearance of its natural slip, and an equalizing current, that is generated in the armature winding with a frequency $f\big|_{eq.c} = f_1 \cdot s$ [17]. The appearance of the equalizing current is a negative phenomenon, as its presence leads to an oscillatory process of currents in the parallel branches of each phase of the armature winding, and consequently to pulsations in the electromagnetic torque and the rotational speed of the rotor [17].

Based on the obtained data from the finite element modeling, the mechanical characteristic of the ISEMC was constructed under the condition of operation of only the IM part, as well as during the combined operation of the IM part and the SM part in the normally excited mode (Fig. 3). The curves 1, 3, and 5 depict the operation of the ISEMC without its SG part (without the field current of the SG) for phase voltage values of U_{phase} =54V, U_{phase} =74V, and U_{phase} =92V, respectively. In this case, regardless of the value of the applied voltage U_{phase}, with the presence of a load (M_c >0), the ISEMC rotor loses synchronism and begins to rotate with slip. With an increase in voltage ($U_{phase} \geqslant U_{rated}$), the value of the maximum torque ($M_{\max}$) increases, and the stiffness of the mechanical characteristic is enhanced, which will fully correspond to the mechanical characteristic of a conventional IM.

During the combined operation of the IM and SG parts of the ISEMC, when the SG part operates in underexcited or normally excited mode (that is, when the condition $I_f \leqslant I_{idle}$ is met), the stiffness of the mechanical characteristic at synchronous rotational speed is ensured by the condition $I_a \leqslant I_f$ (fig. 3, curves 2, 4, 6, at the corresponding phase voltage values U_{phase} =54V, U_{phase} =74V, and U_{phase} =92V). In this case, the maximum permissible value of the load torque M_c, at which the synchronous rotational speed of the rotor ($n = n_{syn}$) is maintained, will be determined by the condition $I_a = I_f$ at the corresponding value of U_{phase}.

Given the condition $I_a > I_f$, the rotor loses synchronism and begins to rotate with slip. In this case, the maximum torque value $M_{\max}$ at the corresponding voltage U_{phase} will occur at the critical slip ($s = s_{cr}$), which does not depend on U_{phase} and will also be equal to s_{cr} when only the IM part of the ISEMC is operating (see fig. 3). When the SG part of the ISEMC operates in u underexcited mode ($I_f < I_{idle}$) at a corresponding constant value of U_{phase} =c*onst.*, a family of mechanical characteristics can also be obtained, which will be located respectively between curves 1 and 2, 3 and 4, 5 and 6, that is, between the mechanical characteristic curves at I_f =0 and at $I_f = I_{idle}$.

To realize the overload capacity of the ISEMC, it is necessary to increase U_{phase} above its nominal value ($U_{phase} > U_{rated}$) (curve 6, fig. 3) while adhering to the stability condition $I_a = I_f$. However, in this case, the SG part of the ISEMC will

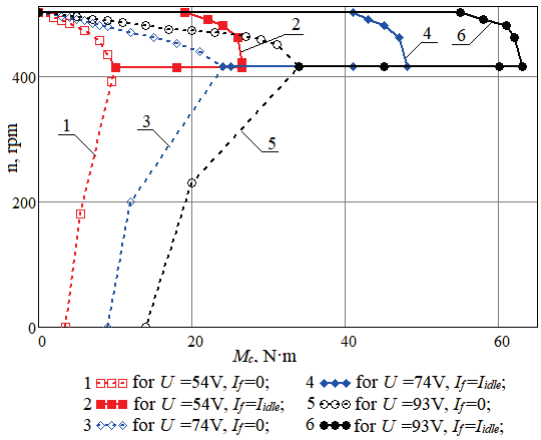

Fig. 3. Mechanical characteristic of the experimental ISEMC, when the SG part operates in the normally excited mode

no longer be able to fully compensate for the reactive power of its IM part, which will lead to the appearance of a reactive component of the armature current ($I_{a.reactive}$), and consequently to a significant decrease in $\cos(\varphi)$ and efficiency (η).

Using finite element modeling, a study was conducted on the starting characteristics of the ISEMC, and the values of the starting torque were obtained depending on the corresponding values of the applied voltage to the armature winding (U_{phase} =54V, U_{phase} =74V, and U_{phase} =92V) (fig. 3), as well as the permissible minimal $U_{phase,min}$ and maximum $U_{phase,max}$ values of the phase voltage of the experimental ISEMC for determining the range of change in the starting torque M_s (fig. 4). To ensure the starting of the ISEMC, its SG part must be disconnected (i.e., I_f =0), because when I_f >0, the SG part of the ISEMC creates a reactive synchronizing torque, that will counteract the electromagnetic torque created by the IM part of the ISEMC at the moment of starting. In this case, as with classical SEMC, asynchronous starting is ensured for the ISEMC.

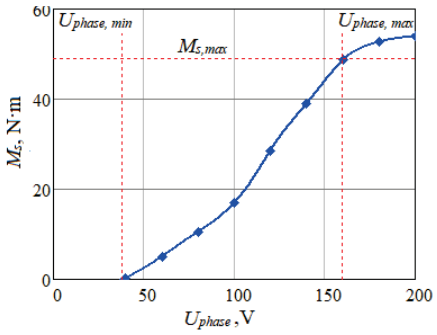

Fig. 4. Dependence of phase voltage on the starting torque of the IM part of the ISEMC

To ensure the maximum permissible starting torque, it is necessary to increase the voltage applied to the armature winding to $U_{phase,max}$, the value of which will correspond to the saturation of the ISEMC's magnetic system, at which the maximum value of the magnetic flux is ensured (see fig. 4).

In fig. 4, the minimal value $U_{phase,min}$ determinate the lower threshold of the phase voltage U_{phase} at which the idle starting of the ISEMC is performed. The determination of this value is important, as it ensures the minimization of the idle losses of the ISEMC.

Thus, when designing an ISEMC to ensure overload capacity, as well as a higher starting torque, it is necessary to calculate the value $U_{rated} << U_{phase,max}$, which will be achieved by the optimal ratio of the number of turns of the combined armature winding and the geometric dimensions and length of the armature core and rotor of the ISEMC.

Based on the results of the circuit-field modeling, the dependence of the armature current on the mechanical power of the ISEMC was obtained at constant operation of the SG part in the normally excited mode, i.e., under the condition $I_a = I_f$, $U_{phase} = U_{rated}$ (curve 1, fig. 5). In this case, the rated value of the ISEMC armature current and its rated power will be determined by the point of symmetry (at P_2 =2.15 kW) of the operating characteristic of the dependence $I_a = f(P_2)$ of the ISEMC at $I_a = I_f$ and $U_{phase} = U_{rated}$ (fig. 5, curve 1).

Under the condition of operation of the SG part of the ISEMC in the normally excited mode for the case, when $P_2 \leqslant P_{2rated}$, the armature current will have only the active component . For the case, when $P_2 \geqslant P_{2rated}$, the reactive power is not fully compensated, so the armature current will have active and reactive components:

$$I_a = \sqrt{I_a|^2_{active} + I_a|^2_{reactive}}. \quad (7)$$

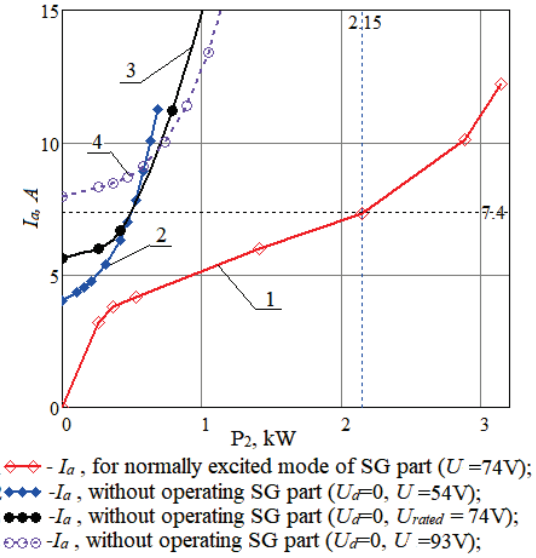

Fig. 5. Dependence of the armature current on the mechanical power of the ISEMC

With a further increase in power P_2 due to an increase in the applied voltage to the armature winding $U_{phase} > U_{rated}$, the content of the reactive component of the ISEMC armature current $I_{a.reactive}$ will increase according to the U-shaped regulating characteristic (see fig. 2). In the underexcited mode of the SG part of the ISEMC in the range of power change $P_2 \leqslant P_{2rated}$, the armature current also have a reactive component $I_{a.reactive}$ due to under-compensation of the reactive power of the SG part of the ISEMC. Fig. 5 also shows the dependences of the armature current on the mechanical power (curves 2, 3, 4) at different values of the applied voltage to the armature winding $U_{phase1} < U_{rated} < U_{phase2}$, when only the IM part of the ISEMC is operating. In this case, the above

dependencies fully correspond to the characteristics of traditional IM. In this case, the armature current will contain a significant part of the reactive component $I_{a.reactive}$ of the ISEMC armature current.

Thus, the issue of the ISEMC power gain in the motor operating mode has been resolved. Typically, according to the ISEMC calculation methodology [15], when determining the winding data, the number of turns of the ISEMC armature winding was determined by the criterion of reducing the idle current, especially for the generator mode of its operation. For the use of ISEMC as a generator, this is appropriate, since the U-shaped regulated characteristic will be shifted to the left as much as possible, which will reduce active losses from the field current in the generator mode. But for the use of ISEMC in the motor operating mode, this limits the power set, which has been established repeatedly in [11]-[13]. Therefore, when designing an ISEMC that will be used only in the motor operating mode, it is necessary that its U-shaped regulated characteristic be shifted to the right as much as possible to increase the power gain margin. That is, it is necessary to maximize the idle current I_{idle} at $U_{phase} = U_{rated}$, since this value I_{idle} determines the symmetry point of the U-shaped nominal regulated characteristic, which determines the normally excited mode of the SG part of the ISEMC, as well as the rated field current $I_{f.rated}$. The increase of the idle current I_{idle} is achieved by the optimal value of the number of turns w of the armature winding and the value of the rated phase voltage U_{phase}.

V. Conclusion

The stability criteria of the ISEMC in the motor operating in the idle and under load modes are determined. The defined stability criteria make it possible to ensure its trouble-free operation with an adjustable power set for the corresponding load while maintaining the cascade synchronous rotor speed.

Using the defined stability criteria of the ISEMC, the regulated properties were investigated and a family of regulated, mechanical characteristics and operating characteristics was obtained in terms of the dependence of the armature current on the mechanical power during the joint and separate operation of the IM and SG parts of the ISEMC motor operating mode.

According to the results of the study, the issue of power gain of ISEMC in motor operating mode was resolved. Recommendations for the selection of winding data for ISEMC depending on its purpose (motor, generator) are given.

***Abstract*—The ways of stabilization of high-current DC glow discharge at medium pressure of 1.33 – 13.3 kPa and discharge currents of 1 – 10 A while diffusion welding is considered. It is shown that the stable DC glow discharge can be provided by inclusion of the ballast resistor with the value of 60 – 80 Ohms in the discharge circuit. However, such a way of glow discharge stabilization is only effective against minor, short-term disturbances. It was also shown that another effective way to stabilize of high-current DC glow discharge in welding is the use of multi-sectioned anode system with the 3 and 5 sections accordingly.**

Keywords—glow discharge stabilization, diffusion welding, multi-section anode, ballast resistor

I. Introduction

Glow discharge at currents of 1 – 10 A and gas pressures of 1.33 – 13.3 kPa is effectively used as an energy source in diffusion welding processes of both homogeneous and heterogeneous materials due to its high energy efficiency, simplicity, and low equipment cost [1]. However, practical use of the glow discharge has revealed a significant drawback limiting its widespread application. Glow discharge as an intermediate form of gas discharges under certain conditions can lose its stability transitioning into a more stable form – an electric arc accompanied by a sharp increase in current [2]. As a result, the heating effect shifts from a dispersed to a locally concentrated one. The action of a concentrated arc discharge on welded samples can lead to melting and destruction of latter that is unacceptable.

Various technological and technical measures are used to stabilize glow discharge while welding. However, regardless of the stabilization measures applied, an active (ballast) resistor must always be included in the glow discharge circuit [3]. The presence of this resistor stabilizes the set burning mode of the discharge under conditions of minimal plasma volume fluctuations. The stabilizing effect of the external ballast resistor is in the fact that any increase in current in the discharge circuit above a steady-state value, including the loss of glow discharge's stability because of transition into an electric arc, results in a proportional increase in the voltage drop across the resistor [4]. Along with constant voltage at the output of power supply, this leads to a decrease in the voltage across the discharge gap and consequently a decrease in electron temperature and ionization rate in the discharge plasma. When the electric field strength in the discharge reaches a certain level, the electron generation rate becomes lower than the recombination rate leading to a decrease in electron concentration and a reduction in the discharge current to its original steady-state value [5].

In practical technological applications of glow discharge, there is a high probability of disturbances caused by the inhomogeneity of the physical and chemical state of the welded parts surfaces being heated by the discharge, local overheating of the gas in the plasma volume and other factors. Existing technical means for stabilizing glow discharge heating process normally respond only after an electric arc had been formed in the interelectrode gap and do not affect the physical processes in the discharge that lead to its transition into an arc [6]. Therefore, despite the large number of research and publications, the problem of stabilizing high-current glow discharge in technological processes such as welding, brazing, thermal and thermochemical metal treatment remains relevant.

The objective of current research is to analyze the processes that accompany the transition of a glow discharge into an electric arc and to improve the methods for stabilizing of high-current glow discharge under welding conditions.

II. Research Methods and Techniques

Theoretical research was based on the scientific principles of gas discharge physics, automatic control theory, and electrical engineering. For experimental investigations, a vacuum workstation for material sputtering equipped with a glow discharge's power supply system was used. Experimental installation scheme of glow discharge is given in Fig.1.

To obtain static current-voltage characteristics (CVC) of glow discharge the direct methods for measuring the main discharge parameters were used. The acquisition and analysis of dynamic characteristics of the steady state and transient glow discharge modes were carried out using a two-channel digital oscilloscope. The characteristics of the arc discharges that formed due to the loss of glow discharge stability were determined by examining the traces (autographs) they left on the sample surface when deflected by a transverse magnetic field.

III. Presentation of the Main Material

Normally, the heating process while welding is carried out using a normal glow discharge in which the cathode spot (heating zone) of the discharge is located on part of the welded samples' surface, which, in this case, act as the cathode of the discharge.

According to the physical literature [7], the CVC of such a discharge is typically considered horizontal, i.e., the

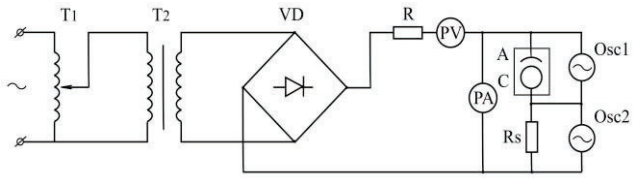

Fig. 1. Electrical scheme of the glow discharge's power supply: *T1* – autotransformer; *T2* – step-up transformer; *VD* – rectifier; *R* – ballast resistor; *Rs* – shunt resistor; *PA, PV* - measuring devices; *A* – anode; *C* – cathode; *Osc* – oscilloscope

discharge voltage is independent of the current. However, under welding conditions with elevated currents of 1 – 10 A and above, the CVC of the discharge becomes slowly falling when the voltage decreases slightly with increasing current. This is a consequence of gas heating in the interelectrode gap and increasing its electrical conductivity. Nevertheless, the descending branch of the CVC is unstable with respect to small deviations. This is explained by the fact that any increase in current relative to the steady state on the descending CVC's branch leads to a further increase in discharge current intensifying the gas heating, which in turn, increases its electrical conductivity. This leads to a reduction in discharge resistance and a subsequent rise in current.

A second critical parameter of the glow discharge's heating mode is the gas pressure in the working chamber, which determines the current density in both the positive column and the cathode spot of the discharge. Increasing the intensity and efficiency of heating process requires higher gas pressure, which leads to a significant radial non-uniformity in the discharge. The current density increases most rapidly along the discharge axis, where the gas is most intensively heated. This can cause contraction (pinching effect) of the discharge and its transition to an electric arc [8].

In both cases, local increases of gas ionization degree within the discharge gap result in increased current and a loss of stability in the preset glow discharge mode, potentially causing its transition to an arc discharge. The power supply's circuit of the glow discharge can be represented as a basic electric scheme that is made up of direct current power source with the open-circuit voltage *E*, an active (ballast) resistor *R*, the total circuit inductance *L* and the glow discharge itself burning between anode *A* and cathode *C* with current *I* and voltage drop *U(I)*. The burning mode of the glow discharge is determined by the point of intersection of the discharge CVC's with the load line $E-IR$ (Fig.2). The electric circuit in steady-state condition can be described by the following equation:

$$E = U(I) + IR + \frac{LdI}{dt} \tag{1}$$

Assuming at a steady state conditions ("*a*" on Fig. 2), we have $U_d = U_0(I_0)$. To assess the stability of the discharge with respect to point "*a*", we will use the method of small deviations of the current δI relative to the steady state I_0 [9]. Then the voltage on the discharge at the new point will have the form of $U(I) = U(I_0 + \delta I)$. Due to the small deviation of δI, when expanding the function $U(I_0 + \delta I)$ into a Taylor series, it is possible to confine with the first two terms:

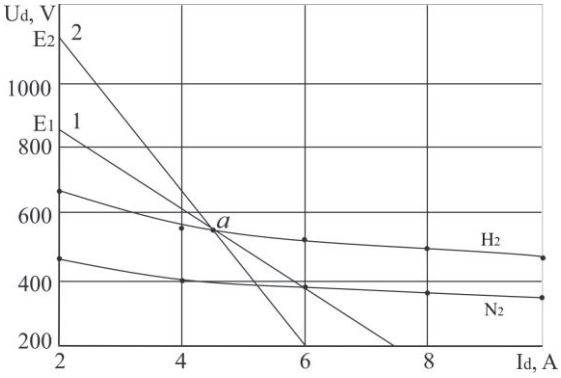

Fig. 2. Static current-voltage characteristics of a glow discharge in a nitrogen and hydrogen plasma and conditional load lines *E–IR* (1 and 2) for different values of ballast resistor

$$U(I_0 + \delta I) = U_0(I_0) + (\frac{\partial U_0}{\partial I_0})\delta I + \ldots \tag{2}$$

In expression (2), the component $\frac{\partial U_0}{\partial I_0} = R_d$ represents the differential discharge resistance.

For the transient process, equation (1) can be rewritten as:

$$L\frac{d(\delta I)}{dt} = E - U_0(I_0) - I_0 R - (R_d + R)\delta I \tag{3}$$

Considering that during stable glow discharge, i.e. in a steady state, the first three components on the right-hand side of the last expression sum to zero, it can be represented by the differential equation:

$$\frac{d(\delta I)}{dt} = -(R_d + R)\frac{\delta I}{L} \tag{4}$$

The solution of this equation is:

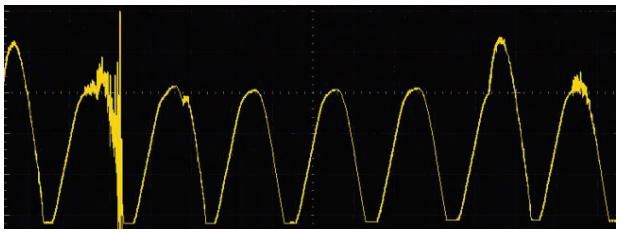
$$\delta I = \delta I(0)\exp\left(-\frac{R_d + R}{L}t\right) \tag{5}$$

where $\delta I(0)$ is the initial maximum value of current deviation.

The differential resistance (R_d) is negative because an increase in current along the descending branch of the CVC leads to a decrease in voltage drop across the discharge. Therefore, to stabilize the specified glow discharge mode, i.e., to ensure that current deviations in the system diminish over time $\delta I \to 0$ the following condition must be satisfied:

$$R_d + R > 0 or R > |R_d| \tag{6}$$

The absolute value of the glow discharge's differential resistance (R_d), determined from experimentally obtained static CVC's in the current range of 1 – 10 A for various gases, is approximately 30 – 40 Ohms. To ensure stable glow discharge operation, the ballast resistor must be 60 – 80 Ohms, which aligns with values proposed in studies [10, 11] and used in practice. However, the experience of practical application of glow discharge under conditions of high current and gas pressure shows that such ballast resistor values are only



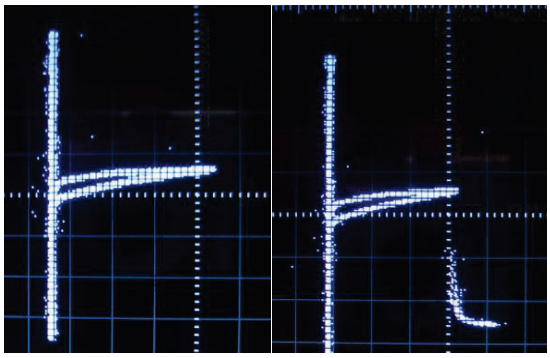


Fig. 3. Occurrence of short-term arc breakdowns in a glow discharge

a) b)

Fig. 4. Dynamic current-voltage characteristics of the glow discharge (a) and the glow discharge – electric arc transition zone (b)

effective against minor, short-term disturbances. In these cases, the formation of a brief arc discharge may eliminate the disturbance (Fig. 3). These disturbances could include fine hair-like projections or localized contaminants on the samples surface, which are melted or vaporized by the arc.

In case of significant disturbances associated with the structure of the welded joint or its thermal deformation during heating, such a level of ballast resistor becomes insufficient to prevent the avalanche development and stabilization of an arc discharge in the interelectrode gap.

The required value of ballast resistor can be estimated by analyzing the dynamic characteristics of the transient process between glow discharge and arc, obtained using a two-channel oscilloscope (Fig. 4). The analysis results show that the transient process is accompanied by a decrease in the voltage in the discharge gap of 150 – 300 V (approximately from 350 – 500 V in a glow discharge to 100 – 250 V in an electric arc). Moreover, this voltage drop increases with the discharge current.

The oscillograms indicate that the transition occurs with only a slight deviation of the discharge current from its steady-state value. Hence, the differential resistance of the discharge $R_d = \frac{dU}{dI}$ in the transition mode significantly increases and reaches several kilo ohms. To satisfy the stability condition (6), the ballast resistance must be of a similar magnitude. However, according to the load line $E - IR$ (line 2 in Fig. 2), incorporating such a high resistance requires increasing the open-circuit voltage of the discharge power supply to several thousand volts. This significantly complicates the power supply's design, operating conditions and safety measures. Therefore, such a method of stabilizing high-current glow discharge cannot be considered efficient or technically feasible.

To analyze other approaches to stabilizing a glow discharge under disturbances, let us consider the discharge-arc

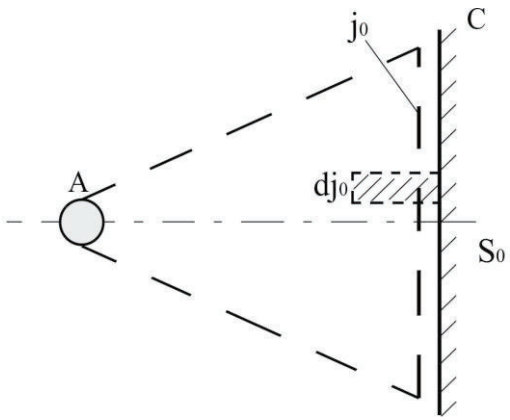

Fig. 5. Scheme of instability formation in a glow discharge: *C* – cathode; *A* – anode; S_0 – cathode heating spot; j_0 – glow discharge's current density; dj_0 – fluctuations in a discharge`s current density

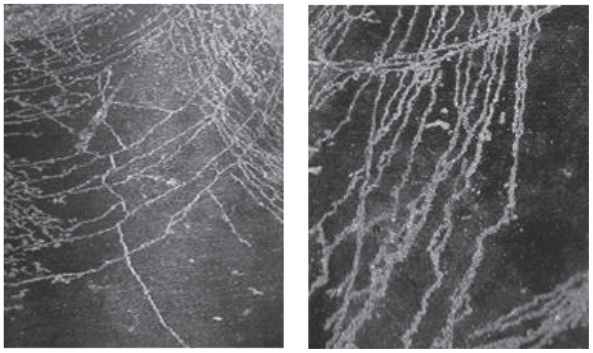
transition process. The initiation of an arc discharge is accompanied by the emergence of a local fluctuation in current density dj_0 against the background of a uniform glow discharge with an average current density j_0 and cross-sectional area S_0 (where S_0 can be taken as the area of the cathode spot, i.e., the heating zone) (Fig. 5). This causes the system transition to a new state characterized by a voltage drop dU and an increase in current dI in the interelectrode gap.

The expression for the differential resistance of the discharge in this transitional state can be written as:



$$R_d = \frac{dU}{dI} = \frac{dU}{S_0 dj_0} \tag{7}$$

Since the values of the differential discharge resistance and the external ballast resistance are commensurate, we replace R_d in expression (7) with R_b. Then we can write expression (7) as follows:

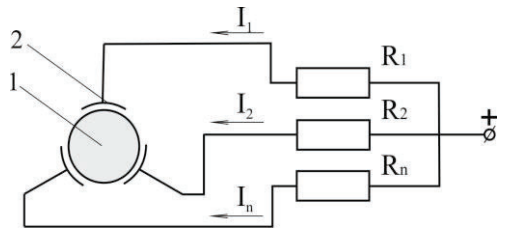
$$S_0 R_b = \frac{dU}{dj_0} \tag{8}$$

From the previous equation, it follows that for a given constant value of ballast resistance (R_b) in order to reduce the voltage drop dU and the differential resistance of the discharge in the transitional state accordingly it is necessary to reduce the area of the discharge cathode spot S_0. The value of δj_0 can be considered constant since the arc autographs (traces) formed during the transition from glow to arc discharge, observed on the sample surface under magnetic field deflection, indicate that as the power of the glow discharge increases, the size of the arc cathode spot also increases (Fig. 6).

As was previously noted, the value of dU depends on the power of the glow discharge and decreases as the current is reduced. The area of the cathode spot in a normal glow discharge, in turn, directly proportional to the discharge current. Therefore, it follows that the conditions for stabilizing glow discharge using an external ballast resistance are more effective for low-power discharges, which are characterized by relatively limited current values. To ensure the stable existence of a high-current glow discharge, it is advisable to divide it into several low-power discharges, the total current and cathode spot area of which are equivalent to those of the original high-power discharge. Such a stabilization approach

a) b)

Fig. 6. Traces of an electric arc arising in a glow discharge at a discharge current of 3 A (a) and 7 A (b), while deflected by a magnetic field



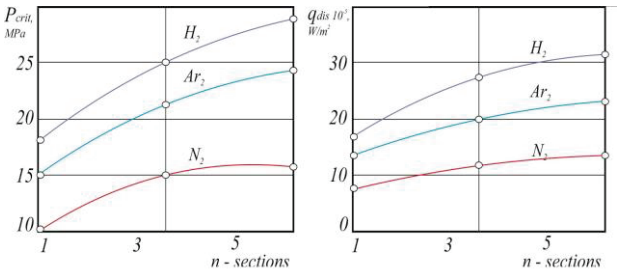


Fig. 7. Heating scheme with multi-sectioned anode: 1 – cathode; 2 – multi-section anode

a) b)

Fig. 8. The effect of anode sectioning on increasing the stability limit of the glow discharge in terms of gas pressure (a) and specific power (b) in different gases: 1 – monolithic contour anode; 3 – three-section anode; 5 – five-section anode

can be implemented by dividing the continuous contour anode of the discharge into several individual segments (sections), each connected to the power supply output through its own ballast resistor (Fig. 7). This configuration corresponds to a parallel connection of ballast resistors, meaning that increasing the number of anode segments allows the resistance values to be raised to the kilo ohm range. As has already been shown, this contributes to improved discharge stability under conditions of high current and gas pressure.

Experimental verification of this hypothesis was carried out by heating cylindrical steel workpieces using glow discharge in nitrogen, argon, and helium. The tests were conducted using both a continuous contour anode and segmented one with 3 and 5 sections accordingly. In the first case, a ballast resistor of 100 Ohms was connected in the glow discharge circuit. In the other two configurations, resistors of 300 and 500 Ohms were connected to each anode segment, respectively. The experimental results (Fig. 8) show that the proposed heating scheme significantly shifts the stability loss threshold of the glow discharge toward higher energy characteristics. Furthermore, even if a low-power arc forms on any section of the cathode, it is absorbed by the corresponding anode segment and has no effect on the discharge behavior in the other segments.

This method allows the usage of ballast resistor for stabilization of a glow discharge more effectively. To eliminate the possibility of an arc formation in the interelectrode gap such number of anode sections should be selected that the current in each segment does not reach the minimum value at which a cathode spot of the arc can form on the cathode (workpiece) surface i.e., the physical conditions for stable arc existence must not be met. For most metals (copper, titanium, iron, tungsten, etc.), the threshold current for arc cathode spot formation does not exceed 1.2 – 1.6 A [12]. Therefore, it is advisable that the current in each anode section not exceed 0.8 – 1.0 A.

IV. Conclusions

Analysis of the dynamic characteristics of the glow-to-arc discharge transition process shows that the value of the ballast resistance required to prevent such transitions and stabilize glow discharge combustion must reach units or tens of kilo-ohms. However, this would require increasing the discharge's power supply voltage to tens of thousands of volts, which is technically unacceptable.

It has been theoretically demonstrated and experimentally confirmed that it is possible to significantly increase the stabilizing ballast resistance, and thus the stability of high-current glow discharge, without increasing the supply voltage, by dividing the discharge into several low-power discharges operating simultaneously in the same working space. This was achieved by segmenting the continuous contour anode, where each individual anode segment is connected to the power source output through its own high-value ballast resistor.

***Abstract*—An analysis of the use of an uninterruptible power supply in combination with an autonomous diesel/gasoline generator was conducted in order to reduce operating costs. Such systems can be used when using an autonomous power generating unit as the only power source for consumers, or in case of emergency or emergency power outages. An analysis of existing autonomous power supply systems was conducted and the relevance of this research direction was substantiated. Load schedules were constructed based on a specific example of an autonomous power generating unit and a certain list of equipment in a private house, depending on the time of day. The developed algorithms were used to assess the effectiveness of using a UPS in conjunction with an autonomous diesel/gasoline generator. The use of a UPS allows you to reduce operating costs by loading the generator to an optimal value of 75-80% of the nominal, saving fuel, reducing maintenance intervals and frequency, and harmful emissions into the atmosphere. The maximum amount of savings, depending on the system operating mode, load nature, and frequency of outages, is from 39% to 76%. Additional energy saving effect can be achieved if this system is additionally equipped with solar panels or a wind generator. This will allow for additional fuel savings and generator life. It is planned to evaluate the effectiveness of this technical solution in future studies.**

Keywords—autonomous electric generator, uninterruptible power supply, autonomous diesel-petrol power plants, renewable energy, electromechanical converter.

I. Introduction

Autonomous power generation units (diesel/gasoline) are vital for various facilities during outages, maintenance, unstable supply, and as backup, especially for remote or autonomous entities [1]. Operation incurs fuel, maintenance, and repair costs. Integrating uninterruptible power supply (UPS) with generators [2] ensures power continuity and significantly reduces operational costs by decreasing generator load and optimizing fuel consumption [3], while enhancing reliability through seamless power source transitions [4, 5]. Although inverter-based systems can have higher initial costs, their integration with generators provides fuel economy, extended maintenance intervals (saving cost/time), longer generator lifespan, and continuous AC power. This study explores innovative approaches to improve energy efficiency and reduce operational costs in autonomous generator systems. UPS integration minimizes low-load generator operation (reducing wear/fuel overuse and emissions [6, 7]), applicable across sectors (industry, healthcare, IT, residential). Literature [8, 9] indicates up to 20% fuel consumption reduction with UPS, and further studies [10, 11] confirm enhanced reliability and reduced outages. The primary goal is to shorten generator runtime, especially during peak loads or brief outages, or to load generators efficiently (75-85%) via inverters. Advanced UPS units provide hours of backup for critical loads [12]. Challenges include cost and complexity, requiring additional equipment and maintenance, though automation improves efficiency and reduces human error [13]. Economically, fewer starts extend engine life and lower maintenance [14]. Thus, UPS integration in autonomous systems offers significant potential for cost reduction and reliability improvement, representing a timely technical and scientific issue.

Aim of the Study. The aim of this study is to evaluate the effectiveness of utilizing a UPS within an autonomous power supply system based on an internal combustion engine electric generator. This will enable the optimization of autonomous power generation units, the reduction of operational expenditures, and the enhancement of system reliability.

Fig. 1 presents the structural diagram of an UPS system specifically designed for electrical installations. The diagram meticulously details the essential components that constitute such a system and clarifies their intricate interconnections. At the core of this configuration lies the UPS unit itself, which assumes the critical role of ensuring a continuous and stable power supply to connected equipment, particularly during instances of primary power source disruptions or failures. The illustration typically depicts the flow of power, control signals, and the integration of various elements that contribute to the system's overall functionality and reliability. The foundation of this sophisticated UPS system lies in the selection of a contemporary UPS unit, with a range of reputable manufacturers such as Victron Energy, Deye, Must, and Daxtromn offering suitable models. A key characteristic of these modern UPS devices is the inclusion

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

of a communication interface, notably the RS485 standard (though other protocols may also be present). This communication port is crucial as it unlocks advanced configuration and customization functionalities for the power converter's operational modes. Engineers and system integrators can leverage this interface to fine-tune various parameters, optimize the UPS's performance characteristics to match specific load requirements, and potentially integrate it with broader energy management or monitoring systems. Furthermore, to achieve additional energy conservation in the proposed system, it can be strategically augmented with renewable energy generation sources, such as photovoltaic solar panels or a wind turbine. The integration of these clean energy technologies offers a dual benefit. Firstly, it reduces the system's reliance on conventional power grids or fossil fuel-powered generators, directly translating into tangible fuel savings, particularly in scenarios where a backup generator forms part of the extended power infrastructure. Secondly, by supplementing the primary power supply with energy harvested from renewable sources, the operational duty cycle and consequently the overall lifespan of any associated electric generator can be significantly extended. This reduction in usage translates to lower maintenance requirements, decreased wear and tear, and ultimately, reduced long-term operational costs. Looking ahead, the authors plan to practically realize and validate the efficacy of this proposed technical solution in their future research endeavors. This implementation phase would likely involve the physical construction and rigorous testing of a prototype UPS system integrated with advanced control mechanisms and potentially incorporating renewable energy sources as described. The subsequent work will then focus on evaluating the system's performance under real-world operating conditions, quantifying its energy efficiency gains, assessing its reliability and stability, and analyzing the economic and environmental benefits associated with such an integrated power supply architecture. The findings from this practical implementation will be crucial in validating the theoretical concepts and paving the way for potential wider adoption of this technology.

Under normal operation, the system channels mains electricity through a contactor, supplying both the UPS and the connected electrical load. Simultaneously, the Battery Management System (BMS) actively monitors the battery's state of charge, precisely controlling the charging and discharging cycles to ensure optimal battery health and longevity. This panel also enables authorized personnel to perform system configuration and adjust operational settings as needed. In the event of a mains power interruption, the system intelligently initiates a generator start sequence based on a comprehensive assessment of the battery's remaining capacity and the current power demand of the connected load. Following a brief warm-up period to ensure stable operation, the system seamlessly switches the power source from the UPS battery to the auxiliary generator via the Automatic Transfer Switch (ATS) contactors (identified as component 4 in Fig. 1 of the accompanying diagram). The specific components strategically chosen and implemented to achieve cost reduction within this overall system design are detailed and systematically listed in Table 1.

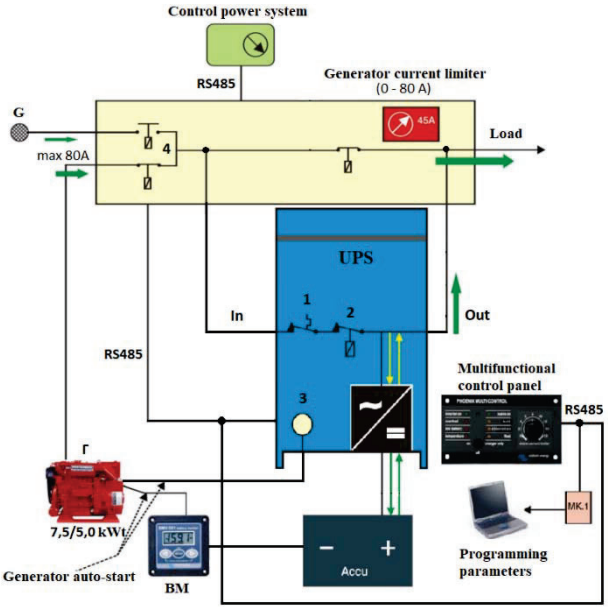

Fig. 1. Configuration of an power supply system based on a UPS: 1 – built-in thermal relay; 2 – protective (emergency) relay; 3 – multifunctional additional UPS input; 4 – input switch (ABA system); G – autonomous generator; BM – battery monitor system

TABLE I. MAIN COMPONENTS OF THE PROPOSED SYSTEM

№	Equipment Designation.	Specifications.	Cost, $
1	Victron MultiPlus 24/3000/70	Power: 2.4 kW; Input Voltage: 187 – 265 V	1350
2	Traction Battery Sunlight (10 PzS 600) LiFePO4.	Rated Voltage: 24 V; Rated Capacity: 600 Ah.	3030
3	SDMO HX 7500 T C	Full Power: 7.5 kVA Rated Active Power: 6.0 kW Fuel Consumption: 2.3 L/h at 75% load	2000
4	Multifunctional Control Panel	Victron Energy GX Touch 50	240
5	Battery State Monitoring System	Battery Monitor BMV-712 Smart 9 - 90B	215
6	Total		6835

Based on the components listed in Table 1, a subsequent calculation of the operational cost reduction effect of the autonomous power generator is performed.

II. MATERIALS AND RESEARCH FINDINGS

To evaluate the operational cost reduction effect, a typical list of equipment for a private house (apartment or townhouse) will be considered. The equipment list is presented in Table 2.

TABLE II. EQUIPMENT LIST

№	Devices	Power, W	Quantity
1	Lighting	20	15
2	TV	120	1
3	Fridge	140	1
4	Water heater	2000	1
5	Submersible well pump	800	1
6	Washing machine	1500	1
7	PC	500	1
8	Router and video surveillance cameras	50	3
9	Vacuum cleaner	800	1
Total			≈5930 W

Figure 2 illustrates a typical consumption profile of the equipment as a function of the time of day, according to the data in Table 2.

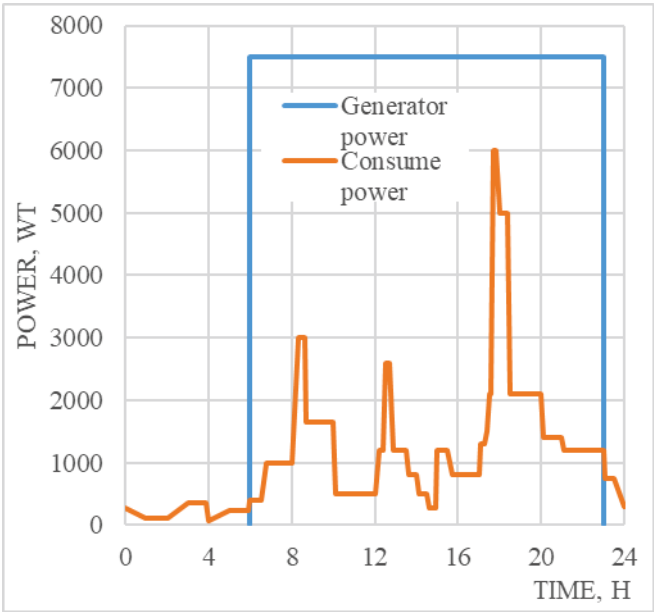

Fig. 2. System using 7.5 kVA generator only

Fig. 2 reveals a morning consumption peak of 3 kW lasting for two hours, a midday peak of approximately 2.5 kW, and an evening peak of 6 kW. Between the morning and midday peaks, and between the midday and evening peaks, consumption is relatively low, averaging around 500 W. Following the evening peak, the average consumption is approximately 1 kW for several hours.

Considering scenarios involving systematic power outages or complete failures of the main electricity supply, and with the assumption that an electric generator with a capacity of 7.5 kilovolt-amperes (kVA) serves as the sole source of power, the generator would be required to operate for a significant duration of 17 hours per day to meet the energy demands of the connected electrical installations. It is particularly noteworthy that for a substantial portion of this operational time, specifically 70% of the 17-hour period, the generator functions under a very light load, consuming less than 15% of its maximum rated power capacity. This indicates a potentially inefficient mode of operation for a considerable duration.

If a UPS with batteries of the necessary type and capacity is added to the system, it can provide the required power for the majority of the equipment's operating time. During peak consumption, the generator automatically starts, and the excess power is used to charge the batteries.

Fig. 3 illustrates the consumption profile of the equipment with the addition of a UPS-type inverter (using the Victron MultiPlus as an example).

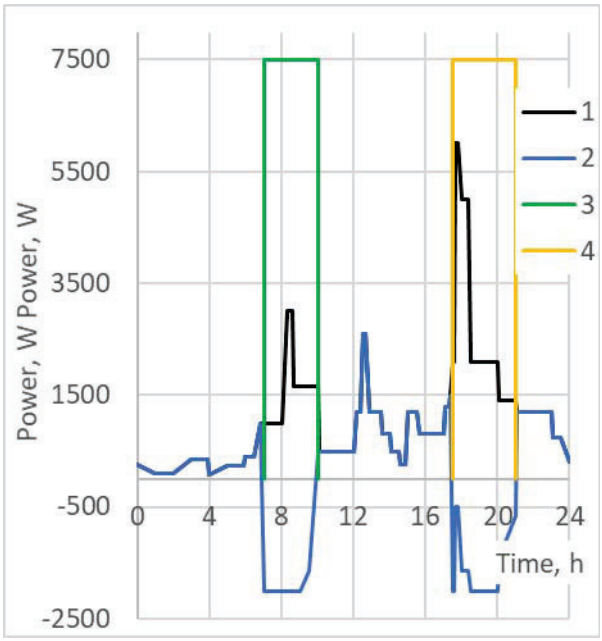

Fig. 3. Load schedule when using a UPS in the system: 1 – consumed load; 2 – UPS power; 3, 4 – generator power

Generator runtime is reduced to 5 hours/day as battery meets most power demands (≤ 2.5-3.0 kW). Generator surplus charges batteries (limited by surplus and inverter capacity, max 2.0 kWh in this example). Battery powers 12 hours of silent operation. Generator runs at up to 70% capacity.

Required battery capacity is lower than without a generator (24 V chosen). Calculation shows discharge to 166 Ah before morning start and 285 Ah before evening start. Formula-based calculation suggests ~658 Ah, thus 24 V/600 Ah commercial batteries are sufficient. A 48 V system would require ~300 Ah.

A 7.5 kVA generator consumes ~1.5 L/h diesel at low load (≤ 25-30%) and 2.3 L/h at 75% load. Standalone operation yields ~25.5 L/day consumption. UPS integration reduces this to 11.5 L/day for the same power, saving 5110 L/year, equating to ~$6643 annually (excluding refueling savings). Detailed operational costs are in Table 3.

Manufacturer recommends oil changes every 150 operating hours (mineral oil). Standalone generator (6205 hours) requires 41 annual changes. UPS integration (1825 hours) reduces this to 12, saving 29 changes/year. With 5 L oil volume, this saves 145 L/year, equating to $725 annually (excluding time/filter costs).

During morning/evening peak emergency outages, the system saves 2070 L fuel/year, ~$2691 annually. With UPS during 8h power, 16h outage (generator 2.5h/day at peak), savings are ~76%. For standalone or systematic outages with UPS, operational cost reduction is ~39%.

Considering equipment/installation costs, payback is ~1-1.5 years for standalone generator replacement and ~2.5-3 years for emergency outage scenarios with UPS.

TABLE III. CALCULATION OF OPERATING COSTS

	Generator only	**Generator + UPS**	**Economy**
Operating hours h/day	17 h	5 h	12 h
Diesel consumption/day	25,5 L	11,5 L	14 L
Annual diesel consumption	9307 L	4197 L (2070L)	5110 L 6643 $/year
Annual oil change	41	12	29
Annual lubricant consumption	205 L/year	60 L/year	145 L/year, costing $705/year
Generator load	15% load for 70% of operating hours	70 %	
Annual fuel and lubricant savings (excluding threefold longer lifespan)	7348 $/year		2691 $/year
Savings over 5 years	36740 $		

Diesel generators have longer lifespans under load (vs. no/low load). Some manufacturers advise ≥ 25-30% minimum load to prevent failure. UPS integration increases generator load from < 15% to 70%, further extending lifespan.

Operating generator with UPS reduces operational costs, specifically the cost per kWh (illustrated in Fig. 4).

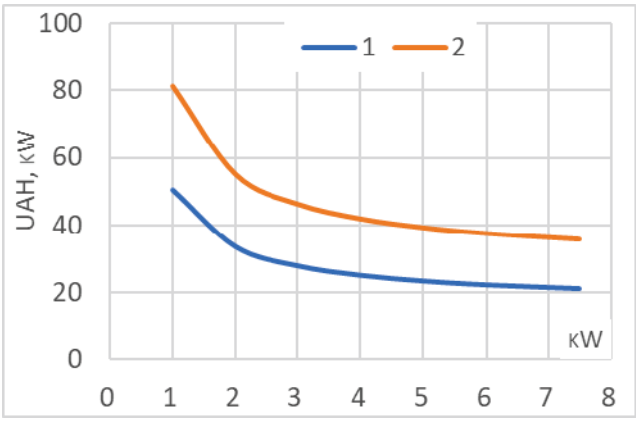

Fig. 4. Cost of electricity based on the output power of the electric generator: 1 – for a 7500 kVA generator with a diesel drive engine; 2 – for a 7500 kVA generator with a gasoline drive engine

CONCLUSIONS

The combined use of an UPS and an autonomous diesel/gasoline generator offers not only silent power delivery but also improved fuel efficiency and reduced maintenance costs. During regular power outages, this integration can lower operational costs by approximately 39%, and by up to 76% in emergency scenarios. These savings result from limiting generator use to 2.5 hours during peak demand, with the remainder supplied by rechargeable batteries, which can be charged from both the grid and the generator. Additionally, this setup minimizes environmental impact through reduced emissions and motor oil waste.

Cost savings depend on factors such as generator capacity, outage schedules, and load characteristics. This study estimates potential maximum savings, noting that actual results may vary. Operational efficiency improves with higher peak consumption level.

***Abstract*—This paper proposes an approach to cyber risk assessment based on a hybrid model. This model combines the capabilities of deep neural networks for network traffic classification and the prediction of parameters for the Lotka-Volterra dynamical system. Such an approach enables the identification of anomalous activity and modelling interactions between attacking and defensive forces in cyberspace, thereby providing a deeper understanding of potential threats. The model was trained and tested on the NSL-KDD dataset. The results demonstrate that the model can effectively classify traffic (accuracy of 0.8006, AUC of 0.9016 on the test set) and predict the coefficients of the Lotka-Volterra model (Mean Squared Error of 0.0027). Analysis revealed that the predicted coefficients of the Lotka-Volterra model exhibit significant differences for normal and anomalous activity. The research of these coefficients and the simulation of the corresponding dynamical systems reveal distinct patterns that correlate with the level of cyber risk, opening new avenues for proactive assessment and management of cyber threats.**

Keywords— cyber risk assessment, neural networks, Lotka-Volterra dynamics, intrusion detection, NSL-KDD, cyber threat modelling

I. Introduction

The relentless growth in the number and complexity of cyber threats in the modern digital landscape poses a critical challenge for organisations in effectively assessing and managing cyber risks [14; 2]. Traditional risk assessment approaches are often static and fail to account for the dynamic interaction between a system's attacking and defensive mechanisms [5]. This leads to a limited ability to predict threat evolution and respond to them adaptively.

Overcoming these limitations requires the development of more sophisticated models capable of capturing the complex dynamics of cyber confrontations. The use of models from other scientific fields is one promising direction. In particular, ecological predator-prey models, such as the Lotka-Volterra model, offer a mathematical framework for describing interdependent populations [15; 12]. Such a model can be adapted to describe the interaction between "attackers" (analogous to predators) and "defensive forces" (analogous to prey or a reactive system) in a cyber environment [15]. The Lotka-Volterra model allows for abstraction to key aspects of the confrontation (e.g., attack propagation rate, effectiveness of defensive measures, system response to intrusion, and the "cost" of maintaining defense), making it attractive for the conceptual modelling of cyber risks.

In this study, we propose a hybrid neural model that integrates network traffic classification for intrusion detection with predicting parameters of the Lotka-Volterra dynamical model. The neural network is trained using network traffic characteristics to distinguish between normal and anomalous activity and estimate the coefficients that determine the interaction dynamics between a potential attack and the system's defense. This approach allows for a transition from merely stating the occurrence of an attack to assessing its potential development and the system's resilience.

This research aims to develop and evaluate the effectiveness of the proposed hybrid model for cyber risk assessment and demonstrate that the predicted parameters of the Lotka-Volterra model form distinct patterns for different types of network activity, thereby enabling qualitative and quantitative evaluation of the cyber risk level.

II. Methodology

The scientific community actively researches the problem of intrusion detection and cyber risk assessment. Machine learning methods, particularly neural networks [4; 8], have found wide application due to their ability to detect complex dependencies in data. Datasets such as KDD Cup'99 and its improved version, NSL-KDD, are frequently used for training and testing intrusion detection systems [10; 13]. Existing approaches based on neural networks demonstrate high accuracy in network traffic classification [1; 7]. However, they are typically limited to stating the presence or absence of an attack.

In assessing cyber risks, the objective extends beyond mere attack detection to include the quantitative or qualitative evaluation of potential harm and its likelihood [3]. However, many existing risk assessment methodologies do not consider

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

the dynamic nature of cyber threats and the interaction between the attacker and the defense system.

Attempts to model the dynamics of cyber attacks and defenses exist. Still, they are rarely integrated directly with intrusion detection systems at the level of model parameterization based on real traffic data. Lotka-Volterra models, describing "predator-prey" type interactions, have been proposed for analyzing malware propagation and other aspects of cybersecurity [11; 12]. These models allow for investigating system stability and the conditions under which an attack can be successful or suppressed [12; 15]. However, a key challenge remains the robust estimation of parameters for these models based on fundamental characteristics of the cyber environment. Our work aims to bridge this gap by using a neural network to predict the coefficients of the Lotka-Volterra model directly from network traffic data.

In developing and evaluating the proposed hybrid cyber risk assessment model, we relied on a carefully selected dataset, adapted a classical dynamical system to the specifics of the subject domain, and utilized modern deep learning methods for model implementation.

Our research used the NSL-KDD dataset [10; 13], an improved version of KDD Cup'99. The NSL-KDD dataset, as noted in [13], was proposed to address some of the problems inherent in the KDD'99 dataset. The advantages of NSL-KDD over the original KDD dataset include the absence of redundant records in the training set, which prevents classifier bias towards more frequent records, and the absence of duplicate records in the test sets, ensuring unbiased performance evaluation. Furthermore, a more balanced distribution of records by difficulty level allows for a more accurate assessment of different learning methods, and a reasonable number of records in the training and test sets enables experiments to be conducted on the complete dataset, ensuring consistency and comparability of research results. Although NSL-KDD may not be an ideal representative of existing real-world networks, according to criticism in [10], it is widely used as an effective benchmark dataset.

The dataset contains files in ARFF format, with 41 features and a class label characterizing each. Basic attributes include connection duration, protocol type (e.g., TCP, UDP, or ICMP), and service (e.g., HTTP, FTP, or SMTP). Other essential attributes include the connection status flag, the volume of transmitted bytes (src_bytes and dst_bytes), as well as various features describing error statistics (e.g., serror_rate and rerror_rate) and time-based traffic characteristics (e.g., count and srv_count). For our study, class labels were aggregated into a binary form: "normal" and "anomaly".

The classical Lotka-Volterra model [12; 15] describes the dynamics of two interacting populations. In the context of cybersecurity, drawing upon previous works [12; 15], we interpret these populations as follows:

$A(t)$ The activity level or intensity of "attacks" is analogous to that of predators.

$Z(t)$ The level of "security" (or protection) or the resources of the security system, analogous to prey or the reactive defense capability of the system.

The Lotka-Volterra system of differential equations, as used in this study, is as follows:

$$\frac{\mathrm{dA}}{\mathrm{dt}} = \alpha \mathrm{A} - \beta \mathrm{A}\, \mathrm{Z}$$

$$\frac{dZ}{dt} = \gamma AZ - \phi Z$$

where the coefficients $\alpha, \beta, \gamma, \phi$ are interpreted and calculated from network features as follows.

Coefficient α represents the intrinsic growth rate of attacks and characterizes the inherent ability of attacks to propagate or emerge without effective countermeasures. A high value α may indicate an aggressive threat nature or a favorable environment for its development. Research calculated this coefficient as the fraction of network sessions exhibiting signs of complex or "hybrid" attacks. Such sessions were identified by the simultaneous exceeding of the 75th percentiles $Q_{0.75}(\cdot)$ for synchronization error rate (serror_rate) and rejection error rate (rerror_rate), which may indicate attempts to bypass defenses or use multiple attack vectors. The calculation is as follows:

$$\alpha = P\big(\text{serror_rate} > Q_{0.75}(\text{serror_rate}) \wedge \text{rerror_rate}. > Q_{0.75}(\text{rerror_rate})\big)$$

The parameter β determines the effectiveness of the defense in neutralizing attacks, reflecting how successfully defensive mechanisms reduce attack intensity through interaction. A high value β implies a strong defensive response per unit of attack. This coefficient was determined as the arithmetic mean of four error indicators: serror_rate, srv_serror_rate (synchronization error rate for services), rerror_rate, and srv_rerror_rate (rejection error rate for services). These indicators can collectively reflect the level of "friction" or confrontation between attacking actions and the system. The calculation is as follows:

$$\beta = \frac{1}{4}(\text{serror_rate} + \text{srv_serror_rate} + \text{rerror_rate} + \text{srv_rerror_rate})$$

The coefficient γ represents the system's protection level or vigilance growth due to interaction with attacks. This parameter reflects the system's ability to adapt and strengthen defensive measures in response to detected malicious activity. A high value γ indicates rapid mobilization of defensive resources. It was calculated as the arithmetic mean of detected anomalies in encrypted services (R_{enc}) such as http_443 and ssh, and the frequency of anomalies in open, unencrypted services (R_{plain}). This allows for assessing the system's response to threats in different visibility segments. The calculation is as follows:

$$\gamma = 0.5 \times \left(R_{\text{enc}} + R_{\text{plain}}\right)$$

Coefficient ϕ models the intrinsic decay or "cost" of maintaining defense. It can reflect the natural decline in the effectiveness of defensive mechanisms over time due to obsolescence, resource depletion, or operational costs of maintaining the security system, even without direct interaction with attacks. This coefficient was calculated as the complement of β:

$$\phi = 1 - \beta$$

We justify this operationalization of coefficients by linking the abstract parameters of the Lotka-Volterra model with specific, measurable characteristics of network traffic. These characteristics can indirectly reflect attack intensity, defense response, and the overall dynamics of the confrontation.

These four coefficients of the Lotka-Volterra model $(\alpha, \beta, \gamma, \phi)$, pre-calculated based on the analysis of characteristics from the entire dataset, serve as target values for training the regression part of the hybrid neural network. Additionally, to characterize the overall threat distribution, the proportions of each attack class were analyzed.

The proposed hybrid neural network is designed with a multi-task learning architecture, a common approach in deep learning [4; 8]. It comprises a shared feature extraction part and two separate output branches for classification and regression.

The input layer accepts feature vectors after preprocessing. A Gaussian noise layer is added to enhance the model's robustness to input data. The shared hidden layers include several fully connected layers with Relu activation functions, batch normalization for stabilizing training, and Dropout layers to prevent overfitting. In the specific implementation, layers with 256 and 128 neurons are used.

The classification branch is responsible for intrusion detection. It consists of several fully connected layers, including a layer with 64 neurons with ReLU and Dropout, an output layer with one neuron and a sigmoid activation function for binary classification into normal and anomalous traffic. The loss function for this task is Binary Cross-Entropy L_{BCE}, which for N samples is calculated as:

$$L_{BCE} = -\frac{1}{N}\sum_{i=1}^{N}[y_i \log(\hat{y_i}) + (1 - y_i)\log(1 - \hat{y_i})]$$

where y_i is the actual class label for the i-th sample, and $\hat{y_i}$ is the predicted probability.

The regression branch predicts the four coefficients of the Lotka-Volterra model. It consists of fully connected layers, including layers with 64 and 32 neurons with ReLU, and an output layer with four neurons and a linear activation function. The loss function for this task is Mean Squared Error (L_{MSE}), which for N samples and $M = 4$ coefficients is calculated as:

$$L_{MSE} = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{M}\sum_{j=1}^{M}\left(c_{ij} - \widehat{c_{ij}}\right)^2$$

where c_{ij} is the actual value of the j-th coefficient for the i-th sample, and $\widehat{c_{ij}}$ is the predicted value.

The target values for training this branch are the pre-calculated coefficients of the Lotka-Volterra model. It is important to note that after the neural network's prediction, the coefficients' obtained values $\alpha, \beta, \gamma, \phi$ are clipped to the range [0,1] before their further use in simulation. This ensures their physical plausibility in the model context, where they often represent fractions or probabilities, and prevents the occurrence of invalid values, such as negative growth rates.

The total loss function of the model L_{Total} is a weighted sum of the loss functions for classification and regression:

$$L_{Total} = w_{BCE}L_{BCE} + w_{MSE}L_{MSE}$$

The weight for the classification loss w_{BCE} is set to 1.0, and for the regression loss w_{MSE}, it is set to 0.2. The model is compiled with the AdamW optimiser [6; 9], which has proven effective for training deep neural networks.

Before being fed into the neural network, the data from NSL-KDD undergoes several preprocessing steps. For numerical features representing byte counts, such as src_bytes and dst_bytes, a logarithmic transformation $f(x) = log(1 + x)$ is applied to reduce the impact of extreme values. A byte ratio is also calculated as a new feature. Categorical features, such as protocol_type and flag, are transformed using one-hot encoding. Other string features are encoded using label encoding. Finally, all numerical features are scaled using standardization to have a zero mean and unit variance. The encoders and the scaler object are trained on the training dataset and saved for subsequent use on the test data and during inference.

III. Evaluation of Hybrid Model Results

The model is trained on the NSL-KDD training dataset, with 20% of this data used as a validation set to monitor the training process and prevent overfitting. Standard callback mechanisms were used to manage the training process. Specifically, a ModelCheckpoint mechanism was employed, which saved the model state that demonstrated the highest Area Under the Receiver Operating Characteristic Curve (AUC) value on the validation set. AUC is a standard metric for evaluating the quality of binary classifiers, indicating their ability to distinguish between positive and negative classes at various classification thresholds. Values close to 1.0 indicate high discriminatory power of the model. Adaptive learning rate reduction (ReduceLROnPlateau) was also implemented, which adjusted the learning rate if the loss function on the validation set did not improve for several epochs. An early stopping technique (EarlyStopping) was applied to prevent overfitting, which terminated the training process if the AUC value on the validation set ceased to increase, restoring the model weights to the state corresponding to the best AUC score.

After training, the model is evaluated on the test set. The primary metrics for the classification task are Accuracy and AUC, and for the regression task, Mean Squared Error (MSE) for the predicted coefficients of the Lotka-Volterra model.

Following the training and configuration of the hybrid neural model according to the described methodology, its evaluation was performed on the NSL-KDD test dataset, and an analysis of the predicted parameters of the Lotka-Volterra dynamics was conducted.

The model training process was monitored using metrics on the training and validation sets. Fig. 1 presents the learning curves, which demonstrate classification accuracy, AUC, and MSE dynamics for the Lotka-Volterra model coefficients.

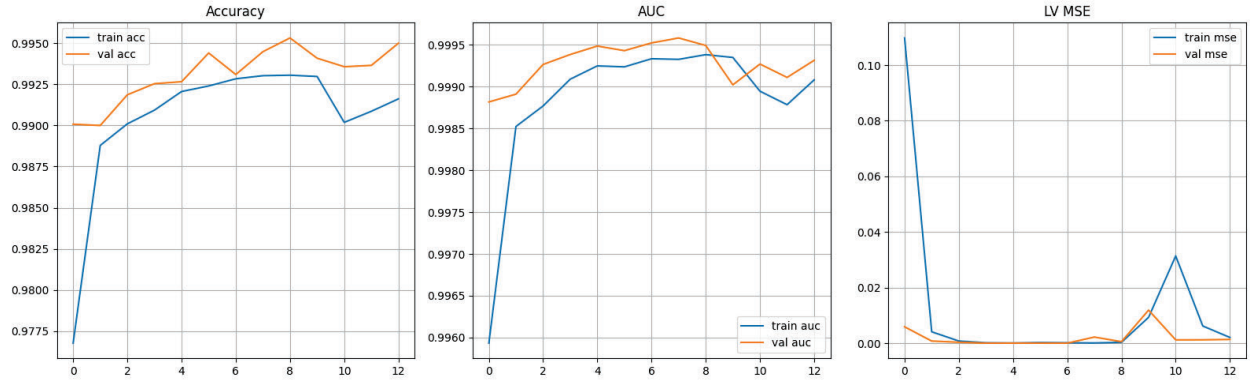

Fig. 1. Model learning curves: (Accuracy) classification accuracy, (AUC) classification AUC, (LV MSE) MSE for Lotka-Volterra model coefficients

Figure 1 visualizes the hybrid model's training process, displaying the dynamics of classification accuracy (Accuracy), AUC, and MSE for predicting the Lotka-Volterra coefficients. Analysis of these curves indicates stable and practical training. The expected increase in accuracy and AUC is observed on both the training and validation datasets, indicating an improvement in the model's ability to classify traffic. Simultaneously, a rapid decrease in MSE for the regression task occurs, demonstrating the model's successful learning of dependencies for predicting the dynamic coefficients. It is essential to note the proximity and synchronous behaviour of the curves for the training and validation sets, especially for AUC and MSE, which suggests good generalization ability of the model and the absence of significant overfitting. This is, in particular, a result of applying the early stopping mechanism, which terminated training upon reaching optimal performance on the validation data, preventing model degradation.

The final performance metrics of the model on the held-out test dataset are presented in Table 1.

TABLE I. MODEL PERFORMANCE METRICS ON THE NSL-KDD TEST SET

Metric	Value
Classification Accuracy	0.8006
Classification AUC	0.9016
MSE for Lotka-Volterra model coefficients	0.0027

Table 1 summarizes the key performance indicators of the developed hybrid model on the held-out NSL-KDD test dataset. The achieved classification accuracy (Accuracy) of 0.8006 indicates that the model correctly identifies most traffic samples. The AUC value is even more indicative, at 0.9016. Such a high AUC value underscores the classifier's excellent discriminatory power and ability to distinguish regular traffic from anomalous traffic at various activation thresholds. For the regression part of the model, which was responsible for predicting the Lotka-Volterra coefficients, a low MSE of 0.0027 was obtained. This indicates the high precision with which the neural network has learned to expect these dynamic parameters. Collectively, these results confirm the high performance of both components of the hybrid model: in anomaly detection and the quantitative assessment of parameters for subsequent dynamic modelling.

After model inference on the test dataset, the predicted Lotka-Volterra model coefficients were analyzed for normal and anomalous classes. The model generated 13592 normal and 8952 anomalous predictions on this set. Descriptive statistics of the predicted coefficients $\alpha, \beta, \gamma, \phi$ of the Lotka-Volterra model for normal and anomalous traffic are presented in Table 2.

TABLE II. DESCRIPTIVE STATISTICS OF THE PREDICTED LOTKA-VOLTERRA MODEL COEFFICIENTS $\alpha, \beta, \gamma, \phi$ FOR NORMAL AND ANOMALOUS CLASSES

Coefficient	Class	Mean	Std. Dev.	Minimum	Maximum
α	Normal	0.0603	0.0325	0.0200	1.0000
	Anomaly	0.0764	0.0256	0.0276	1.0000
β	Normal	0.2243	0.0203	0.1730	1.0000
	Anomaly	0.2514	0.0160	0.1941	0.7318
γ	Normal	0.7386	0.0224	0.2732	0.7533
	Anomaly	0.7348	0.0091	0.5205	0.7532
ϕ	Normal	0.8434	0.0225	0.8127	1.0000
	Anomaly	0.8563	0.0159	0.8196	1.0000

Table 2 shows that the mean values of the four predicted Lotka-Volterra model coefficients systematically differ for normal and anomalous traffic, confirming the informativeness of these parameters for characterizing the system's state. As expected, a higher mean coefficient value α is observed for anomalous traffic (0.0764 versus 0.0603), reflecting a greater inherent ability of attacks to propagate. The mean value of β s is also higher for anomalies (0.2514 versus 0.2243); this may indicate that under attack conditions, the defense system interacts more actively with the threat, leading to greater 'neutralization' per unit of attack, or that the characteristics of the attack itself provoke a more intense response. Somewhat unexpectedly, the mean value of the coefficient γ is slightly lower for anomalous traffic (0.7348 versus 0.7386), which might indicate certain limitations in the system's ability to scale up its defense during some types of anomalies, or that other factors not accounted for in this interpretation γ become dominant. A higher mean value of the coefficient ϕ for the anomalous class (0.8563 versus 0.8434) logically indicates a greater “cost” or faster “depletion” of defensive resources under increased load conditions. These quantitative differences demonstrate the model's ability to distinguish dynamic patterns and provide a basis for a deeper understanding of interaction mechanisms in cyberspace.

A comprehensive approach to visualization was used for the analysis and clear visual illustration of differences in the distributions of the predicted Lotka-Volterra model coefficients for normal and anomalous traffic. Specifically, we constructed histograms (Fig. 2), which allow for assessing the overall shape of each coefficient's distribution and the frequency of occurrence of specific values. For a more detailed comparison of statistical characteristics, such as medians, quartiles, and the presence of outliers, box plots were used (Fig. 3). Additionally, to combine the advantages of both

approaches and gain insight into the distribution density, violin plots were constructed (Fig. 4). This set of visualizations provides a deep understanding of how the predicted parameters of the dynamical system vary depending on the classified type of network activity.

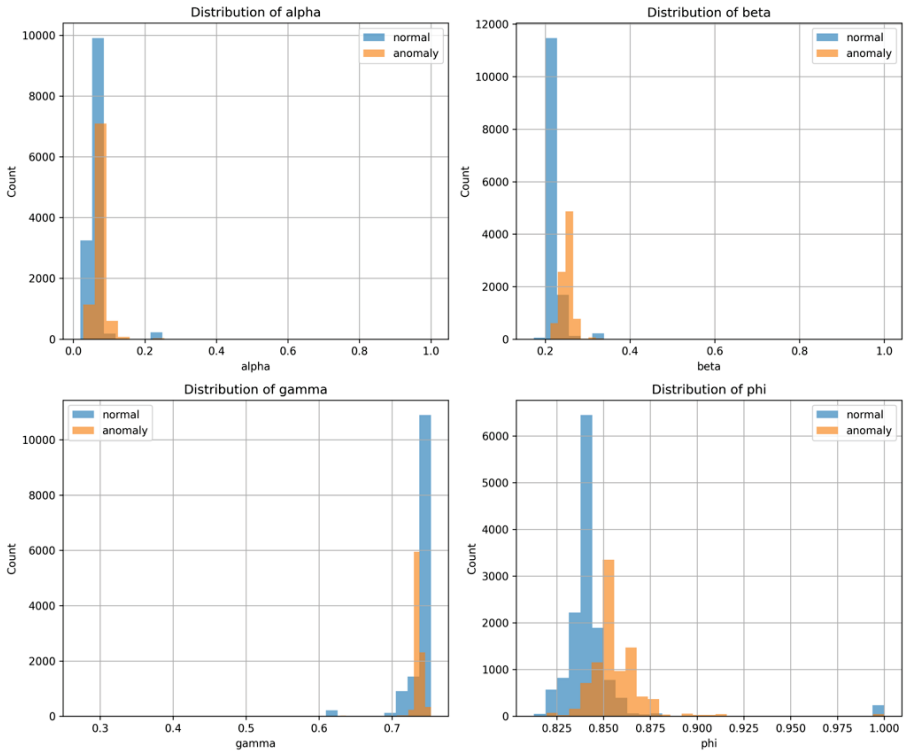

Fig. 2. Histograms of the predicted Lotka-Volterra model coefficients α,β,γ,ϕ distribution for regular (blue) and anomalous (orange) traffic

The histograms in Fig. 2 demonstrate the characteristic differences in the distributions of the predicted Lotka-Volterra model coefficients for regular (blue) and anomalous (orange) traffic, allowing for a deeper understanding of their behaviour.

For the coefficient α (intrinsic growth rate of attacks), the distribution of values for the anomalous class is noticeably shifted to the right. It has a longer right tail than the regular class. This visually confirms the tendency towards higher α values during anomalous activity, indicating its greater potential for independent development.

Regarding the coefficient β (defense effectiveness), the distribution for anomalous traffic also shows a rightward shift and greater variance in values. The peak of the distribution for anomalies is at higher β values, and the distribution itself is wider, which may indicate a more intense interaction between the attack and the defense system.

In the case of the coefficient γ (growth of protection level), although the main concentrations of values for both classes are close, the distribution for the anomalous class is distinguished by a more pronounced left tail. This indicates the presence of a subgroup of anomalous cases with predicted lower γ values, which can be interpreted as situations where the system less effectively strengthens its defense in response to a threat.

Finally, for the coefficient ϕ cost of maintaining defense, the histogram for the anomalous class also shows a rightward shift of the peak and a wider distribution, suggesting a tendency towards higher ϕ values during anomalies. This may reflect greater "costs" of maintaining the security system or its accelerated "depletion" under active confrontation conditions.

Thus, the histograms confirm the quantitative differences and reveal features of the distribution shapes, providing valuable insights for further analysis.

The box plots presented in Fig. 3 provide a detailed view of the statistical differences in the distributions of the predicted Lotka-Volterra model coefficients between normal and anomalous traffic, focusing on key indicators such as medians, interquartile ranges (IQR), and the presence of outliers.

For the coefficient α, the median value for the anomalous class (orange) is higher than for the regular class (blue), indicating a systematically higher level of attack "aggressiveness". A larger IQR is also observed for anomalies, suggesting greater parameter variability under attack conditions.

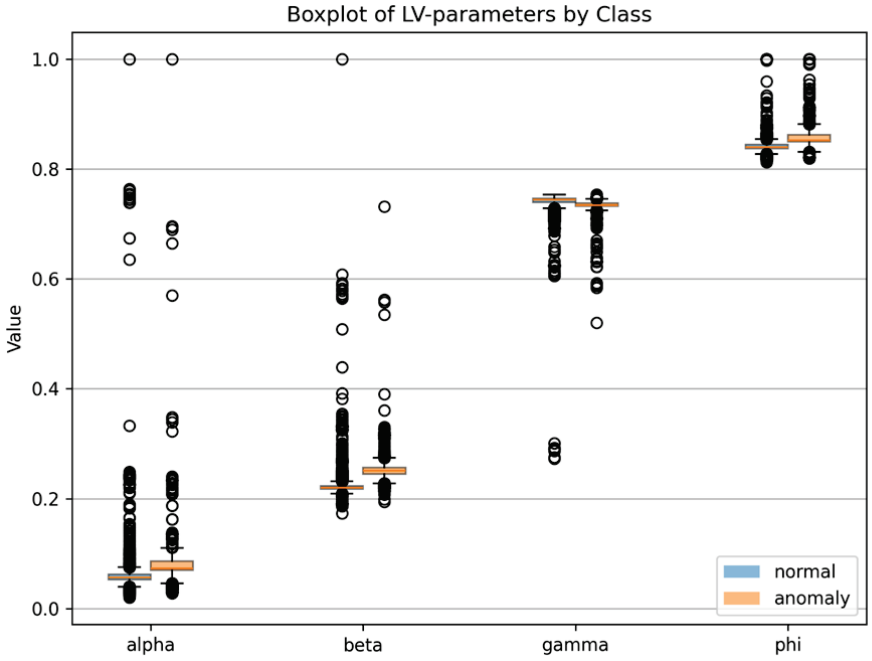

Fig. 3. Box plots of the predicted Lotka-Volterra model coefficients α,β,γ,ϕ for normal and anomalous traffic

A similar trend towards higher values for the anomalous class is observed for the coefficient β, its median and upper quartile for anomalies significantly exceed the corresponding indicators for regular traffic, with the interquartile range also being larger. This underscores the more intense interaction between attack and defense during anomalous events.

In the case of the coefficient γ, the median values for both classes appear quite close. However, the box for the anomalous class shows a wider interquartile range, mainly due to lower values, consistent with a left tail in the histogram. This may indicate greater heterogeneity in the defense system's response to different types of anomalies.

For the coefficient ϕ, the median and the overall range of values (including IQR) for the anomalous class are also shifted upwards compared to the regular class, confirming the trend towards a higher "cost" of maintaining defense during attacks.

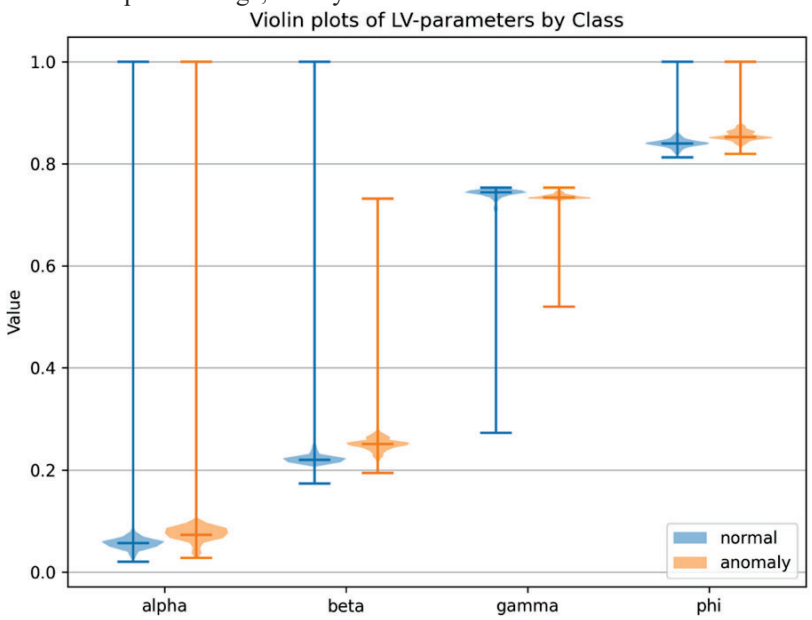

Fig. 4. Violin plots of the predicted Lotka-Volterra model coefficients α,β,γ,ϕ for normal and anomalous traffic

A significant number of outliers, especially for coefficients α and β, indicates the presence of individual network sessions with extreme characteristics, which the model can also identify. Overall, these diagrams convincingly demonstrate that the model classifies traffic and predicts parameters of the dynamical system that are statistically significantly different for regular and anomalous activity, which is key for further risk level assessment.

The violin plots in Fig. 4 effectively combine the informativeness of box plots (displaying the median and interquartile range) with the visualization of distribution density, similar to histograms, allowing for an even more

complete and nuanced understanding of the differences in the predicted coefficients for normal and anomalous traffic.

For coefficient α, the violin plot highlights that although both distributions have peaks at low values, the anomalous class (orange) shows a higher probability density (wider part of the "violin") in the range of higher values, as well as a longer upper tail, indicating a more frequent occurrence of extremely high α values during attacks.

In the case of the coefficient β, the violin plot for the anomalous class is shifted to the right and has a greater width in the value range of approximately 0.23 to 0.28. The distribution is significantly narrower and concentrated around 0.22. This demonstrates higher mean values of β anomalies and a greater diversity of these values.

For the coefficient γ, the violin plots show that the central mass of values for both classes is concentrated in the region of approximately 0.73-0.75. However, the "violin" widens in its lower part for the anomalous class, corresponding to many cases with lower γ values. This confirms observations from histograms and box plots about greater variability and the presence of a left tail in this coefficient's distribution for anomalies.

As seen from the violin plot, the distribution of the coefficient ϕ or the anomalous class is also shifted to the right, with a higher density of values in the 0.85-0.87 range, compared to the regular class, where the density peak is lower.

Thus, the violin plots confirm and complement the conclusions drawn from histograms and box plots, convincingly demonstrating clear and statistically significant differences in the distribution shapes of all four Lotka-Volterra model coefficients depending on the class of network activity. This creates a strong foundation for using these coefficients to model cyber risk dynamics further.

A key validation stage for the proposed hybrid approach is analyzing how the predicted coefficients $\alpha, \beta, \gamma, \phi$ affect the dynamics of the "attack-defense" system, modelled by the Lotka-Volterra equations. To this end, a numerical simulation of the system's development over time was conducted using sets of coefficients individually predicted for each sample from the test set (after their processing to ensure physical plausibility, as described in the methodology). This approach allows not only to state statistical differences in the coefficients but also to visualize and qualitatively assess which interaction scenarios- stable, oscillatory, or escalating-result from particular sets of parameters. The results of these numerous simulations, including time series for "attack" levels $A(t)$ and "defense" levels $Z(t)$, as well as corresponding phase portraits (if they were analysed), were thoroughly systematized. To illustrate the characteristic differences, Figs. 5 and 6 present representative examples of simulation time trajectories for typical cases classified by the model as normal and anomalous traffic. These examples were selected based on prior cluster analysis or analysis of summary characteristics (e.g., maximum amplitude of $A(t)$, time to stabilization, etc.) from the entire set of simulations to best reflect the generalized patterns of system behaviour.

For a typical case of regular traffic, as illustrated in Fig. 5, the Lotka-Volterra dynamics simulation demonstrates behaviour characteristic of a relatively stable system. Initially, a decrease in potential "attacks" $A(t)$ (blue line) is observed, likely due to the initial "defense" level $Z(t)$ (orange line). Although $A(t)$ subsequently begins to rise, reaching a local maximum, the defense system $Z(t)$, after a period of low activity (which may reflect resource saving in the absence of an explicit threat), activates with a delay but effectively enough to reverse the growth trend of $A(t)$ and lead to its decrease towards the end of the simulation period. Importantly, the "attack" level does not get out of control, and the oscillations are either damped or the system returns to an equilibrium state with a low threat level. Such dynamics indicate that the coefficients $\alpha, \beta, \gamma, \phi$ predicted for regular traffic describe a system capable of adequately responding to potential threats and maintaining a secure state.

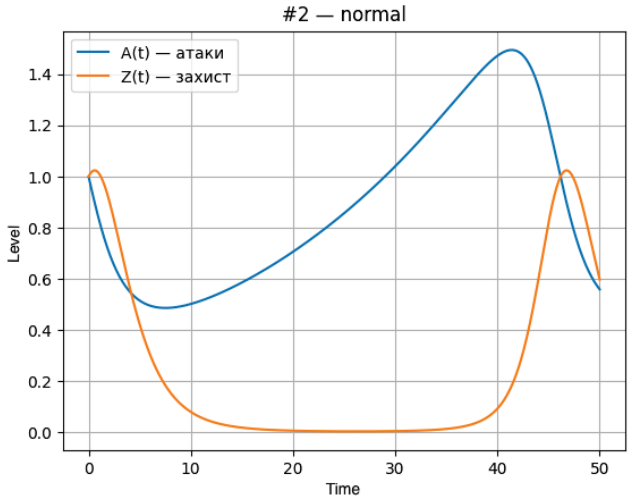

Fig. 5. Example of Lotka-Volterra dynamics simulation for a case classified as "normal"

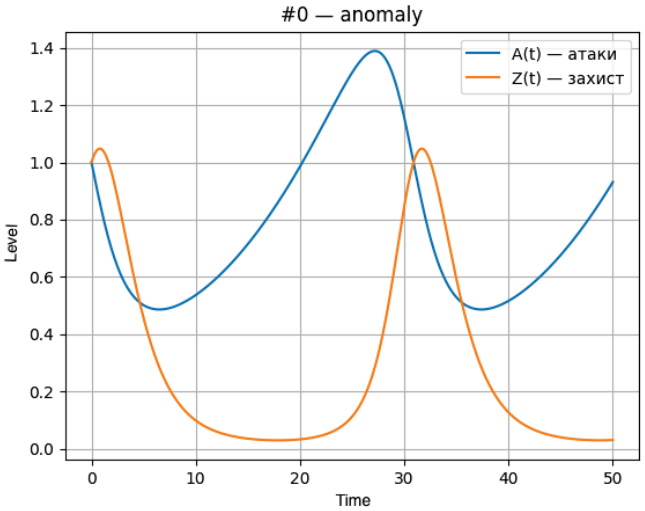

Fig. 6. Example of Lotka-Volterra dynamics simulation for a case classified as "anomaly"

In contrast to regular traffic, the dynamics simulation for a typical case of anomalous traffic (Fig. 6) reveals significantly less stable behaviour of the "attack-defense" system. A sharp increase in the "attacks" level $A(t)$ (blue line) is observed, reaching a considerably higher peak value than regular traffic. Although the "defense" level $Z(t)$ (orange line) also responds to this increase, its response may be insufficient or delayed to suppress the attack effectively. As a result, after a brief decrease, the $A(t)$ level may begin to rise again, or the system enters a mode of pronounced oscillations, where periods of high attack activity alternate with periods of defense

activation. Such oscillatory or uncontrollably increasing dynamics of the $A(t)$ level is characteristic of active cyber confrontation. It indicates a significantly higher level of cyber risk, as the system cannot quickly return to a secure, stable state. This underscores that the coefficients predicted for anomalous traffic describe more dangerous event scenarios.

Analysis of the aggregate simulations conducted for all samples in the test set confirmed these observations on a more general level. It was found that the predicted Lotka-Volterra model coefficients for cases classified as anomalous much more frequently lead to dynamic patterns characterized by either uncontrolled growth of the "attacks" level $A(t)$ (simulating a successful, escalating attack) or sustained high-amplitude oscillations (indicating prolonged active confrontation and system instability). In such scenarios, the "defense" level $Z(t)$ often proves insufficient or fails to respond adequately in time to the attack's development speed.

Coefficients obtained for regular traffic predominantly generate trajectories where the system either quickly returns to an equilibrium state with a low $A(t)$ level or exhibits only minor, controlled oscillations that are effectively suppressed by defensive mechanisms. These more stable and secure trajectories indicate the system's ability to maintain security.

Thus, the simulation results not only confirm the binary classification (normal/anomaly) but also provide qualitatively new information about the nature of the potential threat or system stability. This opens up the possibility for a more granular assessment of cyber risks: for example, Distinguishing anomalies that lead to rapid escalation from those that result in prolonged but less intense confrontation. Consequently, the proposed hybrid approach, which combines classification with dynamic modelling, has significant potential for creating more informative cyber risk assessment systems that go beyond merely stating the fact of an intrusion and allow for predicting possible consequences.

Although the obtained results demonstrate the proposed hybrid approach's effectiveness, it is essential to discuss some of its aspects and potential limitations for a complete picture. The latter, at the same time, point to possible avenues for future research.

Firstly, although the NSL-KDD dataset is a standard for comparison [13] and allowed us to demonstrate the method's viability, it is worth noting that it was created quite some time ago and may not fully cover the spectrum of modern threats [10]. However, the developed architecture of the hybrid model and the very principle of combining classification with the prediction of dynamic parameters are flexible. This creates a prospect for adapting and applying this approach to newer, more representative datasets, which can confirm the results and potentially increase the model's accuracy and relevance in modern conditions. Training or fine-tuning the model on such data is a logical next step.

Secondly, using the Lotka-Volterra model is undoubtedly a simplification of complex processes in cyberspace [12; 15]. Nevertheless, this model is a useful abstraction that allows for understanding and visualizing key dynamic aspects of the "attack-defense" interaction, which are often ignored in static risk models. The value of the approach lies not so much in an absolutely precise imitation of reality as in obtaining a qualitatively new level of understanding of the potential development of a situation.

Thirdly, one of several possible operationalizations is the method for determining the Lotka-Volterra model coefficients $(\alpha, \beta, \gamma, \phi)$ based on specific NSL-KDD features [12; 15]. When transferring the approach to other datasets where the feature set may differ, adaptation of these formulas or development of new methods for their calculation corresponding to the available data will be required. This opens a direction for further research on universalization or developing alternative ways to parameterize dynamic models based on network data.

Furthermore, the regression part of the neural network, like many deep learning models [4], has "black box" characteristics. Although the model demonstrates good accuracy in predicting coefficients, a detailed study of the influence of individual input features on the predicted dynamic parameters requires the application of interpretability methods. This is also an important direction for future work, allowing for a better understanding of the model's internal logic.

Therefore, acknowledging the existing limitations, we consider them not so much as shortcomings that negate the obtained results, but rather as stimuli for the further development and improvement of the proposed hybrid approach to dynamic cyber risk assessment.

IV. Conclusions

This work proposed and investigated a hybrid neural model for cyber risk assessment that combines network traffic classification with the prediction of parameters for the Lotka-Volterra dynamical model. Experiments on the NSL-KDD dataset showed that the model can effectively detect anomalous activity, achieving an accuracy of 0.8006 and an AUC of 0.9016, and predict the Lotka-Volterra model coefficients $(\alpha, \beta, \gamma, \phi)$ with a Mean Squared Error of 0.0027. Importantly, the predicted coefficients significantly differ for normal and anomalous network sessions.

Analysis of the predicted Lotka-Volterra model coefficients and subsequent simulation of the "attack-defense" dynamics demonstrated that the proposed approach allows for identifying a threat and assessing its potential development and interaction with the defense system. Different patterns of Lotka-Volterra model dynamics, corresponding to various traffic classes and sets of coefficients, can serve as indicators of the cyber risk level, providing a more detailed picture of the security state than traditional intrusion detection systems.

The practical significance of the work lies in the possibility of creating more informative decision support systems in cybersecurity. Such systems would allow us to respond to already detected incidents and proactively assess potential threats by analyzing the dynamic characteristics of interactions in cyberspace, considering the modern threat landscape.

Further development of this approach may include validating the model on more modern and diverse datasets reflecting current cyber threats; investigating the impact of different neural network architectures and methods for interpreting Lotka-Volterra model coefficients; integrating the model with real security monitoring systems to assess its effectiveness in an operational mode; extending the Lotka-Volterra model to account for more factors, such as different types of attacks, defensive strategies, and adaptation mechanisms; conducting a sensitivity analysis of the Lotka-

Volterra model to the predicted coefficients; and a deep investigation into the interpretability of the neural network's regression part to identify key network features influencing the dynamic parameters.

***Abstract*— This study investigates the effect of nitrate-containing additives on the morphology and elemental composition of black chromium coatings. The coatings were deposited on AISI 304 stainless steel substrates, which are widely used as a structural material in nuclear power applications, using the galvanostatic electrolysis method. The synthesized coatings were characterized by scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDX). The results showed that increasing the concentration of aluminum nitrate in the electrolyte led to a noticeable increase in the size of surface cracks in the coatings. Specifically, when aluminum nitrate was introduced while sodium nitrate was excluded from the electrolyte, the crack size increased by a factor of 12.5. The addition of aluminum nitrate also reduced the average crystallite size within the coating by a factor of 3.5 to 7. Despite this reduction, the presence of large crystallites (600–800 nm) was observed across all examined samples. A specimen formed in an electrolyte containing 0.1 mol/L aluminum nitrate without sodium nitrate exhibited larger crystallites compared to one formed in an electrolyte with the same aluminum nitrate concentration but with added sodium nitrate. The crystallite sizes were 250 nm and 100 nm, respectively. Elemental analysis confirmed that all coating samples were composed of chromium and oxygen, with no detectable aluminum. Based on EDX point analysis, the likely chemical formulas of chromium oxides in various oxidation states were calculated and correlated with specific points on the coating surface. These findings indicate that the coatings predominantly consist of heat-resistant and hard chromium (III) oxide, along with contributions from chromium (IV) oxide and mixed-valence chromium (II,III) oxide.**

Keywords—black chromium, protective coatings, chromium oxides, scanning electron microscopy, energy dispersive X-ray spectroscopy.

I. Introduction

Nuclear energy plays a significant role in ensuring stable electricity generation both in Ukraine and globally. Its continued development remains a strategic priority. At the same time, the long-term operation of nuclear power plants has become a current reality, and this trend is expected to persist. This evolution of the industry poses a number of challenges for researchers and engineers, one of the key ones being the extension of the service life of structural materials. Consequently, the development of new materials is a critical issue for enhancing the safety and resilience of nuclear energy systems.

One of the key factors significantly affecting the service life of structural components is corrosion. It is well known that equipment failures caused by corrosion lead to increased radiation exposure for personnel and the environment, as well as substantial economic losses. The materials used in nuclear power systems are exposed to various types of corrosion damage, including general corrosion, environmentally assisted cracking, stress corrosion cracking, irradiation-assisted stress corrosion cracking, flow-accelerated corrosion, and microbiologically influenced corrosion [1–4]. Another specific, yet equally hazardous form of corrosion is pitting corrosion of stainless steel, which occurs in aqueous environments containing chloride ions. The presence of chloride ions in solution can lead to the breakdown of the passive film that serves as the protective barrier for stainless steel. Once this film is compromised, localized pits—known as pitting sites—form on the surface. Within these pits, an acidic environment with a low pH develops, promoting aggressive localized attack. The progression of these pits into the bulk of the material can lead to significant degradation of its mechanical properties.

One of the materials widely used in the core and primary circuit of existing nuclear power plants is austenitic stainless steel, such as AISI 304 [5–8]. Its advantages include resistance to general corrosion in aqueous environments even at elevated temperatures, good ductility, and relatively low cost compared to other types of stainless steels. However, as no material is entirely immune to degradation, AISI 304 is still susceptible to corrosion damage, particularly pitting, crevice, and intergranular corrosion. Although various approaches exist for protecting materials against corrosion, it is essential to consider both economic feasibility and overall effectiveness. In this context, the use of protective coatings represents a practical and cost-efficient compromise.

Since the structural components of nuclear power plants operate under prolonged exposure to elevated temperatures and radiation [9–11], the protective coatings used must also meet the stringent requirements of heat resistance, mechanical strength, and radiation tolerance. In current research on Accident-Tolerant Fuel (ATF) concepts, particular attention is given to chromium-based coatings as a short-term solution to enhance fuel performance under accident conditions [12–15]. Of notable interest is the passive chromium (III) oxide film, which retains its protective properties even at high operating temperatures. Additionally, chromium (III) oxide is well known for its exceptional hardness. These properties make it highly suitable for meeting the performance demands placed on materials used in next-generation nuclear power plants [16–22].

Currently, scientific literature frequently explores various methods for the formation of metal oxide coatings, including sol-gel techniques, vapor-phase deposition methods, dip-coating, and electrochemical deposition—each with its own

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

specific advantages and areas of application. This study emphasizes the electrochemical method as the most technologically versatile and economically justified approach to the fabrication of chromium oxide coatings.

In the formation of metal oxide coatings via electrochemical methods, two primary modification strategies can be employed: altering the electrolysis regime and modifying the electrolyte composition. The influence of electrolysis parameters has been demonstrated in [11, 12], particularly in discussions on the impact of pulsed deposition modes on the morphology of black chromium coatings. At the same time, the development of novel electrolyte compositions remains a promising area of research.

Significant efforts are being made to develop composite coatings based on black chromium [5, 6]. Studies have shown that the quality of black chromium coatings can be influenced by the use of catalytic additives. Several investigations [4, 6] have employed compounds containing nitrate ions as such additives. In the work of M. Aguilar-Sánchez [14], it was demonstrated that the addition of KNO_3 to the electrolyte promotes the formation of a "black" chromium deposit, whereas a similar electrolyte without the nitrate-containing additive yields a "white" chromium deposit. It was found that the black deposit consists predominantly of chromium (III) oxide, while the white deposit is composed of chromium (III) hydroxide. The researchers concluded that the reduction of the nitrate ion during electrolysis plays a critical role in determining the nature of the compounds that form the coating layer.

However, the effect of the combined introduction of aluminum nitrate and sodium nitrate on the morphology and elemental composition of black chromium remains insufficiently studied. Of particular interest is the investigation of how these components influence the crystalline structure, grain size, and crack formation patterns, as these factors have a direct impact on the performance characteristics of the coatings.

In our previous studies [5], it was established that black chromium coatings synthesized without the addition of modifying components contain chromium oxides in various oxidation states, specifically CrO_2, Cr_2O_3, and Cr_3O_4. These phases were identified using X-ray diffraction (XRD) analysis and were found to exhibit different degrees of thermal and electrochemical stability. Of particular importance is the presence of Cr_2O_3, as it is the most stable passivating phase, responsible for imparting protective properties to the coating.

This research aims to investigate the effect of aluminum nitrate and sodium nitrate additives on the morphology and elemental composition of the resulting surface layer. Establishing a correlation between the electrolyte composition and the characteristics of the coating's surface layer will make it possible to determine the most balanced solution composition for forming continuous protective layers on stainless steel.

II. Materials and Methods

A. Coatings formation

AISI 304 stainless steel was used as cathode. Coatings were formed by electrodeposition in a galvanostatic mode. Tested black chromium coatings were applied to both sides of each plate on a total area of 4 cm^2. The process was carried out in a cell with a working capacity of 500 ml. The anode was a platinum wire. Compositions of electrolytes, mol/L: 2.5 CrO_3, 0.3 H_3BO_3, 0.01 $Ba(OH)_2$, 0…0.1 $Al(NO_3)_3$ with addition of 0.06 $NaNO_3$, and 0.1 $Al(NO_3)_3$ without the addition of $NaNO_3$. Electrolysis was carried out at a current density of 50 A/dm^2 for a duration of 40 minutes. The electrolyte temperature was maintained at room temperature.

B. Surface morphology and elemental characterization.

The analysis of surface morphology and elemental composition of the obtained samples was performed using a ZEISS EVO 40XVP scanning electron microscope equipped with an INCA Energy 350 energy-dispersive microanalysis system (Carl Zeiss, Germany; Oxford Instruments, UK). Surface images were acquired by detecting secondary electrons (SE) generated during scanning of the surface with an electron beam. Secondary electron excitation was achieved by irradiating the samples with an electron beam at an energy of 15–20 keV. The acquired micrographs were processed using SMARTSEM and ImageJ software environments.

III. Results and Discussion

A. Morphology analysis

The coatings obtained after electrolysis exhibited a matte black appearance, uniformly covering the entire surface of the sample. The visual appearance of the coatings remained unchanged regardless of the concentration of $Al(NO_3)_3$ and $NaNO_3$ in the electrolyte.

The micrographs in Fig. 1 and Fig. 2, captured at different magnifications, provide a detailed view of the surface morphology of the formed coatings. It is evident that the largest cracks are characteristic of the coating obtained from the black chromium electrolyte containing 0.1 mol/L $Al(NO_3)_3$ without the addition of $NaNO_3$. Cracks in the chromium oxide layer of this sample are clearly visible even at a magnification of 500× (Fig. 1, d), with the largest cracks exceeding 2.5 μm in width.

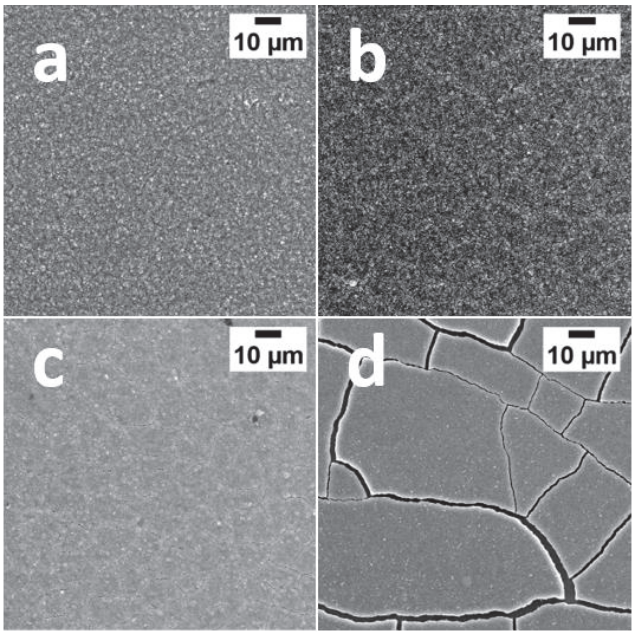

Fig. 1. SEM images of black chromium coatings, obtained from electrolytes with addition of 0 (a); 0.05 (b); 0.1 (c) and 0.1 mol/L without the addition of $NaNO_3$ (d)

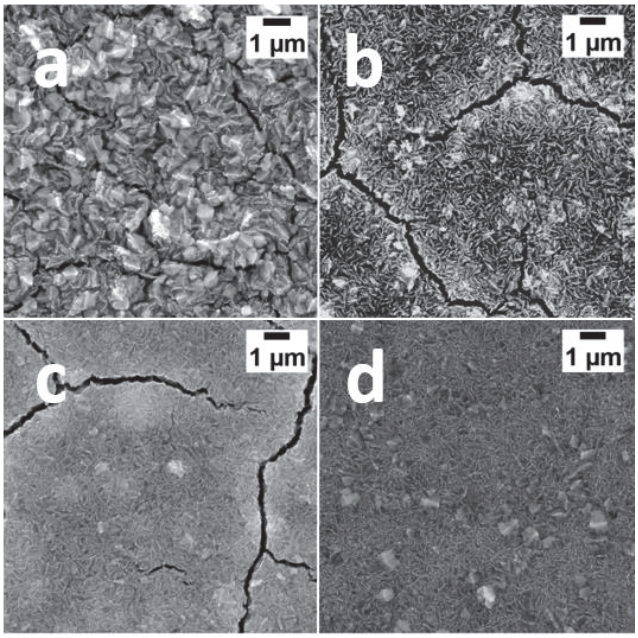

Fig. 2. SEM images of black chromium coatings, obtained from electrolytes with addition of 0 (a); 0.05 (b); 0.1 (c) and 0.1 mol/L without the addition of $NaNO_3$ (d)

It was also noted that the areas of the coating confined by cracks in this sample are internally homogeneous and structurally intact. In contrast, cracks in the coatings of samples formed from electrolytes containing $NaNO_3$ become visible only at a magnification of 5000× (Fig. 2 a, b, c), with the average crack width in each case measuring approximately 0.2 μm. These findings suggest a well-defined correlation between crystallite size and the concentration of nitrate-containing compounds, with increased concentrations leading to smaller crystallite sizes. The images in Fig. 2 show that the addition of $Al(NO_3)_3$ alters the configuration of the crystallites forming the coating. The surface acquires a finer-grained crystalline structure, which positively affects the mechanical, optical, and decorative properties of the coating. The coating obtained from electrolytes without the addition of $Al(NO_3)_3$ has an average crystallite size of approximately 700 nm. As the concentration of $Al(NO_3)_3$ increases, the crystallite size decreases. According to Fig. 2 (b), the crystallite size is about 200 nm when 0.05 mol/L $Al(NO_3)_3$ is added. In Fig. 2 (c), the crystallite size is reduced by half with an increase in $Al(NO_3)_3$ concentration to 0.1 mol/L.

The samples also contain inclusions of larger crystallites with an average size of approximately 600 nm. As shown in the micrograph in Fig. 2 (d), the sample obtained from the electrolyte without $NaNO_3$ exhibits a significant number of large crystallite inclusions, with an average size of 777 nm. In contrast, the average size of the smaller crystallites, which predominantly form the coating, is much lower, around 250 nm. Therefore, the presence or absence of $NaNO_3$ in the electrolyte plays a decisive role in determining crack size and influences the crystalline structure of the coating.

B. Analysis of elemental composition

The elemental composition of each coating sample was determined at four distinct points, the locations of which are shown in Fig. 3. At each point, Chromium and Oxygen were detected, with their respective contents presented in Table 1. Aluminum was not detected in the composition of any of the coatings.

Analyzing the data presented in Table 1, it was found that the introduction of $Al(NO_3)_3$ into the black chromium electrolyte at varying concentrations leads to a decrease in the proportion of chromium in the compounds forming the coating. Accordingly, the oxygen content increases. However, when $Al(NO_3)_3$ is introduced and $NaNO_3$ is excluded from the electrolyte composition, the chromium content in the resulting compounds is the highest among all the samples. Based on the results of the EDX analysis, the possible chromium oxide compounds were also calculated. According to these calculations, the surface of the black chromium coating formed without the addition of $NaNO_3$ contains chromium (III) and chromium (IV) oxides. Compound CrO_2 was identified at the beam impact points located on large, bright crystallites within the coating (Fig. 3d, point 2). In contrast, Cr_2O_3 was detected in areas where the coating consists of finer, darker crystallites. The coating obtained from the electrolyte without the addition of $Al(NO_3)_3$ (Fig. 3a) consists of crystallites similar in size to the large crystallites embedded in the previously discussed coating (Fig. 3d). Elemental analysis revealed that at points 2 and 4 (Fig. 3a), the coating consists of chromium (IV) oxide, which is consistent with the observations made for the coating obtained from the electrolyte without $NaNO_3$. At points 1 and 3 (Fig. 3a), the coating consists of Cr_2O_3 and Cr_3O_4. The identified oxides are consistent with the X-ray diffraction (XRD) results reported in publication [5].

The coating obtained from the electrolyte with the addition of 0.05 mol/L $Al(NO_3)_3$ consists of CrO_2, Cr_2O_3, and Cr_3O_4 compounds. The coating formed from the electrolyte containing 0.1 mol/L $Al(NO_3)_3$ consists of CrO_2 and Cr_2O_3 compounds. Coatings synthesized with both $Al(NO_3)_3$ and $NaNO_3$ additives predominantly consist of finer crystallites but also contain inclusions of larger crystallites, which is consistent with the observations described above. The most heat-resistant, chemically stable, and hardest of the identified chromium oxides is chromium (III) oxide — Cr_2O_3. It has a melting point of 2435 °C. Additionally, its hardness reaches up to 29.5 GPa, providing coatings based on it with excellent wear resistance. Among the detected compounds, the least thermally stable is chromium (IV) oxide — CrO_2. At temperatures around 277 °C, it becomes thermally unstable and transforms into the more stable Cr_2O_3 phase. Another oxide identified in the coating is Cr_3O_4, a mixed-valence chromium (II,III) oxide, with a melting point of 1705 °C [22].

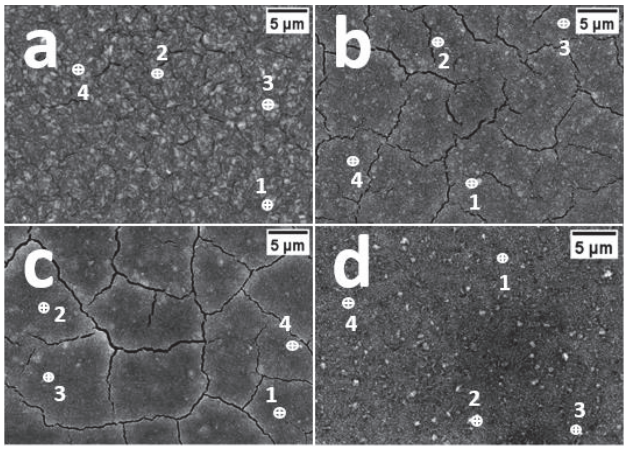

Fig. 3. EDX analysis points locations on black chromium coatings, obtained from electrolytes with addition of 0 (a); 0.05 (b); 0.1 (c) and 0.1 mol/L without the addition of $NaNO_3$ (d)

TABLE I. AVERAGE ELEMENTAL COMPOSITION OF COATINGS OBTAINED BY EDX POINT METHOD

Concentration of $Al(NO_3)_3$ in electrolyte, mol/L	Element	Concentration at a point, wt.%				
		1	2	3	4	Mean
0	Cr	68.49	61.92	59.03	63.51	62.50
	O	31.51	38.08	40.97	36.49	37.50
0.05	Cr	63.15	61.69	67.88	71.09	66.30
	O	36.85	38.31	32.12	28.91	33.70
0.1	Cr	68.18	67.88	61.86	62.39	64.99
	O	31.82	32.12	38.14	37.61	35.01
0.1 without $NaNO_3$	Cr	66.12	62.18	68.68	69.16	65.28
	O	33.88	37.82	31.32	30.84	34.72

Thus, the performed elemental analysis of the coatings demonstrates that varying the electrolyte composition allows for controlled formation of chromium oxides with different degrees of thermal stability. The most desirable outcome is a predominance of Cr_2O_3 in the coating, a thermodynamically stable and hard phase that ensures high wear and heat resistance. The obtained results confirm that the targeted formation of this phase can be achieved by optimizing the ratio of $Al(NO_3)_3$ and $NaNO_3$ additives in the electrolyte.

IV. CONCLUSIONS

Morphological analysis revealed that increasing the concentration of $Al(NO_3)_3$ in the electrolyte leads to a finer crystalline structure in the coating. However, this also results in larger crack formation. Elemental analysis confirmed the presence of chromium and oxygen. Based on the Cr:O ratio, the coatings were found to contain chromium oxides such as CrO_2, Cr_2O_3, and Cr_3O_4. Notably, no aluminum was detected in the coatings. Coatings produced from electrolytes without $NaNO_3$ exhibited larger cracks that covered broader surface areas compared to those formed with $NaNO_3$, while the crystal size remained nearly unchanged. All samples obtained from electrolytes containing $Al(NO_3)_3$ exhibited a fine-crystalline structure. The presumed oxide phases are characterized by high hardness and thermal resistance, confirming the effectiveness of the resulting chromium-based compositions as protective coatings.

***Abstract*— The magnetic interference created by the electromagnets of the orientation control system inside a small spacecraft is considered. Depending on the two variants of the electromagnet design, an analysis of the magnetic field strength in the central part of five satellite models was comply. It was established that the level of magnetic interference created by a cylindrical electromagnet is 2–4 times lower than the magnetic field of a square current winding under the condition of the same magnetic moments and length. It is shown that the specific magnetic moment per unit of mass and electric power of a cylindrical electromagnet is approximately ten times higher than that created by a square current winding.**

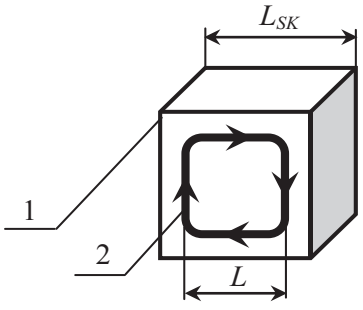
Keywords—magnetic compatibility, spacecraft, magnetic field, electromagnet, current winding.

I. Introduction

One of the trends of the modern stage of development of space technology is the use of a wide variety of spacecraft (SC) for the study of outer space around the Earth. Based on the number of mission objectives, SCs differ in size, mass and time of operation in orbit depending on the parameters of the payload equipment. For the simplest mission objectives, the payload and the SC itself can be made with minimized overall dimensions and mass. Reducing the cost of delivering a satellite to low orbit to a level of less than \$ 10^3 per 1 kg has created a real boom in the development of very small spacecraft. Today, small spacecraft are classified by approximate overall dimensions and mass in the following ranges. Spacecraft with overall dimensions from 0.2 m to 0.5 m and a mass from 10 kg to 100 kg are considered micro-satellites. Spacecraft with overall dimensions from 0.1 m to 0.2 m and a mass of 1–10 kg belong to the class of nano-satellites. Even smaller spacecraft in size and mass are classified as pico-satellites [1–5].

Regardless of the size of the satellite, the reliability of its operation depends on many factors, one of which is the stable standard orientation of the spacecraft in orbit. A common property of small spacecraft is the control of the angular position due to the mechanical interaction of the magnetic moment of the orientation system and the Earth's magnetic field. To ensure the reliability of stabilization of the angular position of the satellite in orbit, the magnitude of the magnetic moment created by such electromagnets can be estimated at the rate of 0.2 A·m^2 per 1 kg of the mass of the SC. Therefore, such electromagnets usually have a design consisting of a cylindrical current winding that magnetizes a core made of soft magnetic material [6]. However, minimization of the size and mass of small spacecraft has prompted the use of a simplified design for electromagnets in the orientation control systems of micro- and nano-satellites in the form of a rectangular flat current winding without a ferromagnetic core. The magnetic moment created by such a simplified design electromagnet is equal to the multiplication of the ampere-turns by the average area of the turn of the flat winding. Simplification of the design of the electromagnet has a positive effect on the cost of its development and manufacture. However, the location of the payload equipment actually inside the current winding exacerbates the problem of magnetic compatibility of the spacecraft [7].

Therefore, it seems appropriate to analyze and compare the magnitude of magnetic interference created by electromagnets of two different types inside a small spacecraft, depending on its overall dimensions.



II. The Aim and Objectives of the Study

The aim of the work is to compare the magnitude of magnetic interference created by different types of electromagnets of the spacecraft's orientation control system to ensure magnetic compatibility inside the satellite.

The dependences of the magnitude of the magnetic field of interference created by different types of electromagnets for five satellite models, the overall dimensions of which increase linearly, are subject to study.

III. Output Conditions for Comparative Analysis of the Magnetic Field of Different Types of Electromagnets

The work compares the value of the magnetic field strength modulus created by a square current winding and a cylindrical electromagnet on an axis that crosses the center of the SC. For ease of comparison, the magnetic field is calculated on an axis that is perpendicular to the plane of the square current winding and passes through its center. In this case, a square winding with a current I and the number of turns N_w is considered thin enough so that its plane S_w is calculated as the square of the side L, and it itself is located in the boundary plane of the spacecraft (Fig. 1).

- Fig. 1. –The location of the square current winding on the boundary of the spacecraft: 1 – satellite model, 2 – square current winding.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

Such assumptions allow us to use the well-known formula [8] for a square coil to calculate the magnetic field strength modulus H_w on the central axis:

$$H_w = \frac{IN_wL^2}{2\pi}\left[x^2 + \left(\frac{L}{2}\right)^2\right]^{-\frac{3}{2}}, \quad (1)$$

where x – coordinate of the field observation point lying on the central axis perpendicular to the winding plane.

In order to ensure a correct comparison of the magnetic field of two types of electromagnets: a square current winding and a cylindrical electromagnet, the following assumptions are made in the work.

The cylindrical electromagnet has the same values of the following parameters as the square current winding: length L, mass m and the created magnetic moment M. When calculating the magnetic field strength, the cylindrical electromagnet was considered to be located at the location of one of the sides of the square winding (Fig. 2). The center of the coordinate system in this calculation was tied to the center of the electromagnet core, and the axis of the applique was directed along its axis of symmetry in the direction of the created magnetic moment.

To analyze the influence of the overall dimensions of the spacecraft on magnetic compatibility, a set of five generalized satellite models with the main parameters given in Table I. The smallest of the models has parameters that are close to the student nano-satellite PolyITAN-1, which was launched into orbit on June 19, 2014 [9]. The parameters of the average of the considered micro-satellite models are similar to the Ukrainian Micron spacecraft, which was launched into orbit on December 24, 2004. To simplify the comparison, the considered spacecraft models have a cubic shape, similar to the CubeSats standard, with an overall size of L_{SK}. In addition, Table I contains data on the mass m_{SK}, the magnetic moment M created on each spatial coordinate axis, the average daily electric power W_{SK} and the voltage U of the power system.

IV. Magnetic Field of a Square Current Winding

According to the definition of the magnetic moment created by a square current winding, its plane should be as technologically possible as possible. Therefore, in practice, the length of the side of the square winding L is usually 80–90% of the L_{SK} of the overall size of the satellite. Using the data from Table I, the parameters of the square current winding were calculated for the corresponding satellite model. It was assumed that the used electric power W_w of the square winding is equal to 15% of the average daily power W_{SK} of the satellite.

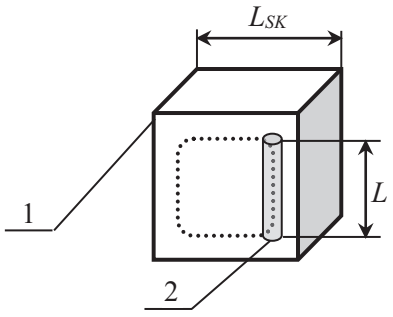


Fig. 2. – The location of the cylindrical electromagnet at the location of the current winding: 1 – satellite model, 2 – electromagnet.

From which the formulas were used to calculate the current and resistance R of the square current winding:

$$I = \frac{0.15 \cdot W_{SK}}{U}, \quad (2)$$

$$R = \frac{U^2}{0.15 \cdot W_{SK}}. \quad (3)$$

The number of turns N_w of the square winding was calculated based on the value of the nominal magnetic moment by the formula:

$$N_w = \frac{M}{I \cdot L^2}. \quad (4)$$

The specific resistance ρ of the winding wire per 1 m of its length was calculated as the ratio of the winding resistance to the total length of the wire:

$$\rho = \frac{R}{4L \cdot N_w}. \quad (5)$$

According to the obtained values of specific resistance from the reference tables of copper wire properties, its diameter d_w was selected. Using these tables of copper wire properties, the mass of the square current winding wire m without fastening elements and insulation was determined (Table II).

Using (1), the magnetic field strengths were calculated as a function of the relative distance x/L to the center of the square current winding in five satellite models (Fig. 3).

From the analysis of the magnetic field dependences shown in Fig. 3, it follows that the increase in the mounting density, which is inherent in the reduction of the satellite size, leads to an increase in the absolute value of the magnetic interference. Thus, for smaller spacecraft, the magnetic interference created by the electromagnet exacerbates the problem of magnetic compatibility of the equipment inside the satellite. This is especially true for elements and devices that are located at distances less than $L/2$ from the current winding.

In addition, from the coincidence of the results of the calculation of magnetic interference for the first and second models of the nano-satellite, it follows that the magnetic field strength of the square winding is proportional to the created magnetic moment M and inversely proportional to the cube of the linear size L^3:

$$H \sim \frac{M}{L^3}. \quad (6)$$

Therefore, an increase in the second model by two times the size of the square winding and eight times the nominal magnetic moment compared to the first model leads to the same absolute values of the magnetic field at the same relative distances x/L.

TABLE I. Basic Parameters of Satellite Models

№	L_{SK}, m	m_{SK}, kg	M, A·m^2	W_{SK}, Watt	U, Volts
1	0.1	1.0	0.2	1.5	3
2	0.2	8	1.6	6	6
3	0.3	25	5	13.5	12
4	0.4	50	10	24	24
5	0.5	75	15	37.5	30

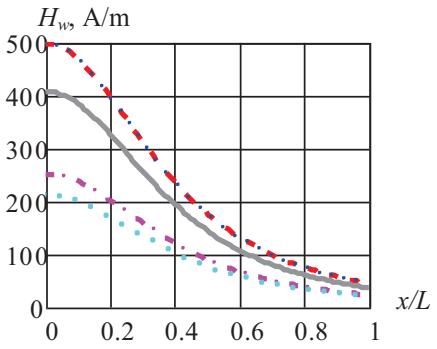

Fig. 3. –Dependences of the magnetic field as a function of the relative distance to the center of the square winding for five spacecraft models with overall dimensions: red line – 0.1 m; blue line – 0.2 m; gray line – 0.3 m; purple line – 0.4 m; cyan line – 0.5 m..

Analysis of the magnetic field distribution inside all models of the spacecraft indicates the possibility of a decrease in the absolute value of the magnetic interference magnitude with distance from the square winding.

V. MAGNETIC FIELD OF A CYLINDRICAL ELECTROMAGNET

The main design variant of the electromagnet of the satellite orientation control system is based on a combination of a cylindrical current winding, inside of which is located an inductively magnetized core [6]. To generalize the comparison of the magnetic field created by a cylindrical electromagnet, its mathematical model is considered simplified according to [10]. In this design variant, almost all the magnetic moment is created by a ferromagnetic core in the form of a cylinder, having a length L and a diameter D_c. The values of the geometric parameters of the cylindrical electromagnet were chosen to ensure equality with the following parameters of a square winding: length L, mass m, outer diameter of the current winding D_{out} and the created magnetic moment M. In addition, Table III contains data on the diameter of the ferromagnetic core D_c, the number of turns N_{el}, the diameter of the wire d_{el} of the cylindrical winding, the used electric power W_{el} and the maximum possible magnetic moment M_{max} at the power specified in Table II. The values of the parameters of the five cylindrical electromagnets presented in Table III are not optimal for the described satellite models, but are close to those actually created and used in spacecraft.

TABLE II. PARAMETERS OF A SQUARE CURRENT WINDING

№	L, m	N_w	ρ_w, Ohm/m	W_w, Watt	d_w, mm	m, kg
1	0.08	469	0.3	0.2	0.255	0.0753
2	0.16	416	0.15	0.9	0.38	0.274
3	0.25	480	0.15	2	0.38	0.494
4	0.37	487	0.225	3.6	0.315	0.512
5	0.45	395	0.225	5.625	0.315	0.505

TABLE III. PARAMETERS OF A CYLINDRICAL ELECTROMAGNET

№	L, m	D_{out}, mm	D_c, mm	N_{el}	d_{el}, mm	W_{el}, Watt	M_{max}, A·m^2
1	0.08	12.5	6.0	4672	0.24	0.021	0.6233
2	0.16	20.0	9.6	6516	0.35	0.049	8.613
3	0.25	18.9	10.0	7864	0.37	0.125	17.9
4	0.37	15.7	10.8	6918	0.35	0.44	28.4
5	0.45	14.2	10.0	5294	0.38	0.845	32.0

The calculation of the magnetic field strength inside the satellite was performed assuming the location of a cylindrical electromagnet instead of a square current winding along one of its sides. The formula from [10] for the magnetic field strength H_{el} in the plane of the central cross-section of the electromagnet was used for the calculation:

$$H_{el} = \frac{4M}{\pi^2 k L D_c} \int_0^{\infty} I_1\left(\lambda \frac{D_c}{2}\right) K_0\left(\lambda \sqrt{x^2 + \frac{L^2}{4}}\right) \sin\left(\frac{\lambda k L}{2}\right) d\lambda, \quad (7)$$

where K_0 and I_1 – modified Bessel functions, x – the coordinate of the field observation point lying on the axis that intersects the center of the spacecraft and is perpendicular to its boundary side. The coefficient k is determined according to the 1% deviation of the longitudinal dependence of the magnetic field created by a cylindrical current winding on its axis of symmetry, and lies within 0.75–0.95 [10].

For five satellite models, the dependences (Fig. 4) of the magnetic field strength as a function of the relative distance x/L were obtained using (7).

From the analysis of the dependencies presented in Fig. 4, it follows that the magnitude of the magnetic field created by a cylindrical electromagnet inside the satellite increases with a decrease in the overall size of the spacecraft. This trend is explained by an increase in the mounting density with a decrease in the size of the satellite, which requires a larger magnetic moment per unit volume to ensure the reliability of the orientation control system. The absolute values of the magnetic field, as in the case of a square winding, are proportional to the magnetic moment and inversely proportional to the cube of the overall size at the same mounting density. In addition, a comparison of the magnitudes of the magnetic field created by a square winding (Fig. 3) and similar values in Fig. 4 determines the following advantage of using a cylindrical electromagnet. The magnetic interference created by a square winding is 3–4 times greater than that created inside a similar model of a satellite by a cylindrical electromagnet.

The rationality of using cylindrical electromagnets is demonstrated by the graphs in Fig. 5. The graphs show the dependences of the magnetic field reduction in the case of replacing the square winding with a cylindrical electromagnet, calculated by the formula:

$$\Delta = \frac{H_w}{H_{el}}. \quad (8)$$

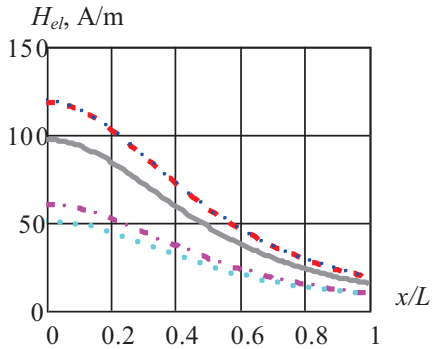

Fig. 4. – Dependences of the magnetic field as a function of the relative distance to the center of the boundary surface, where the electromagnet is located, for five SK models with overall dimensions: red line – 0.1 m; blue line – 0.2 m; gray line – 0.3 m; purple line – 0.4 m; cyan line – 0.5 m.

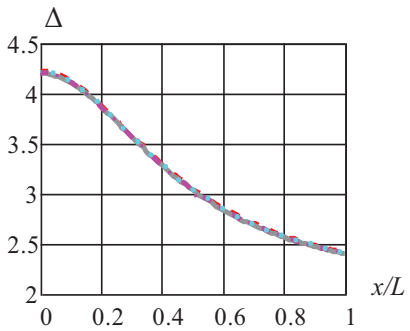

Fig. 5. –Dependencies of the ratio of the magnetic field of a square current winding and a cylindrical electromagnet, for five models of spacecraft with overall dimensions: red line – 0.1 m; blue line – 0.2 m; gray line – 0.3 m; purple line – 0.4 m; cyan line – 0.5 m.

The lines of the graphs in Fig. 5 are similar to those used in Fig. 3 and Fig. 4 and correspond to the sizes of the five satellite models considered. The coincidence of functional dependencies of magnetic interference reduction when using a cylindrical electromagnet instead of a square current winding demonstrates independence from the absolute values of the spacecraft dimensions when the specified conditions for replacing the magnetic source are met.

VI. Specific Magnetic Moment of the Electromagnet of the Satellite Orientation Control System

Among the limiting parameters that determine the direction of optimization of space technology, the used electric power and the mass of the device are always considered. Therefore, when comparing two variants of the design of an electromagnet, it is advisable to analyze the dependence of its main operating characteristic, magnetic moment, on electric power and mass. The last two parameters can be used to determine the specific mass and power of the magnetic moment in accordance with the five spacecraft models considered in the work. Let us introduce the specific magnetic moment for a square current winding M_w and for a cylindrical electromagnet M_{el} according to the formulas:

$$M_w = \frac{M}{m\ W_w}, \tag{9}$$

$$M_{el} = \frac{M}{m\ W_{el}}. \tag{10}$$

The constructed graphs of the dependence of the specific magnetic moment for two variants of the electromagnet design on the overall size of the spacecraft are shown in Fig. 6 by red and blue lines. For a direct comparison of these results, Fig. 6 shows the ratio of the specific magnetic moments M_{el}/M_w created by a cylindrical electromagnet and a square current winding under the comparison conditions specified above.

From the analysis of the obtained results it follows that the specific magnetic moment of a cylindrical electromagnet is many times greater than that of a square current winding. At the same time, the general trend is an increase in the efficiency of using cylindrical electromagnets instead of current windings with a decrease in the overall dimensions of the satellite. The scatter of the results of the ratio of specific magnetic moments M_{el}/M_w is explained by the non-optimal parameters of the cylindrical electromagnets used for comparison.

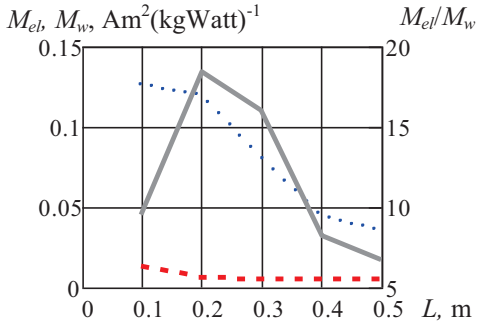

Fig. 6. – Dependences of the specific magnetic moment on the overall size of the spacecraft: for the current winding – red line, for the cylindrical electromagnet – blue line, scale on the left; the ratio of the specific magnetic moments of the cylindrical electromagnet and the square current winding as a dependence on the overall size of the spacecraft – gray line, scale on the right.

VII. Conclusions

As a result of the analysis of the magnetic interference created by the square current winding in the central part of the nano-satellite, a magnetic field strength level of 250 A/m was obtained. For micro-satellites, a similar level of magnetic interference is 50–150 A/m with a tendency to decrease with increasing overall size of the spacecraft. In the case of using a cylindrical electromagnet with the same length and magnetic moment instead of a square current winding, the indicated levels of magnetic interference are reduced by 2–4 times regardless of the size of the satellite. The specific magnetic moment per unit of mass and used electric power, which is created by a cylindrical electromagnet, is 5–15 times greater than that of a current winding.

***Abstract*—The growing demand for secure, long-range wireless communication in the Internet of Things (IoT) has led to widespread adoption of LoRa technology. However, traditional LoRa implementations remain vulnerable to quantum computing attacks. This paper proposes the integration of post-quantum cryptographic algorithms, specifically Niederreiter encryption and LDPC codes, into LoRa systems to enhance their resilience. We explore the theoretical foundation of these algorithms, practical implementation strategies, and their impact on system performance. Experimental results and security analyses validate the feasibility of this approach, establishing a pathway for future-proof secure communication in LoRa-based IoT networks.**

Keywords— LoRa, post-quantum cryptography, IoT security, LDPC, Niederreiter, ESP32, UTM mapping, wireless encryption

I. Introduction

LoRa (Long Range) technology has become a cornerstone of many IoT applications due to its low power consumption, extended range, and simplicity. However, as quantum computing advances, the cryptographic primitives currently used in LoRa implementations (e.g., AES, ECC) face potential vulnerabilities. Quantum computers could, in theory, solve discrete logarithm and integer factorization problems exponentially faster than classical computers, rendering current encryption mechanisms obsolete.

To address this issue, researchers have proposed the adoption of post-quantum cryptographic (PQC) algorithms that remain secure even in the presence of quantum computing capabilities. Among the most promising PQC candidates are code-based cryptosystems, such as the Niederreiter scheme, which is based on the hardness of decoding linear error-correcting codes like LDPC (Low-Density Parity-Check) codes.

In this paper, we propose a novel hybrid system that enhances existing LoRa communication by integrating PQC methods. We provide a theoretical background on Niederreiter encryption and LDPC codes, describe an implementation architecture for embedding them into LoRa systems, and evaluate the practical impact of such integration in terms of security, performance, and scalability

.

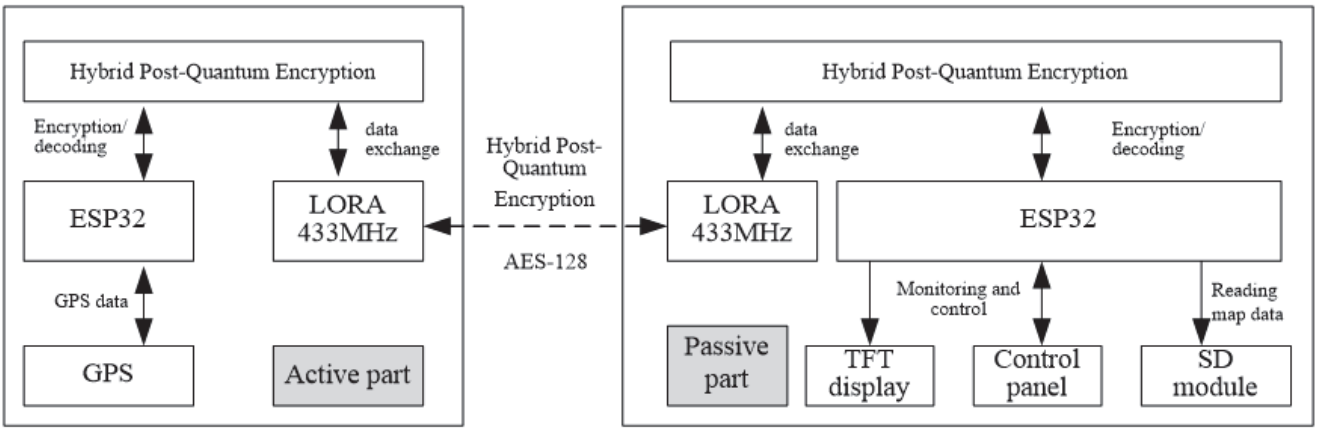

Fig. 1. Concept Post-Quantum Algorithms Encryption

II. Main Research

Several prior works have explored the intersection of LoRa security and emerging cryptographic techniques. Traditional enhancements focus on improving AES key exchange protocols or introducing ECC-based mutual authentication. However, these are not inherently resistant to quantum attacks. On the other hand, research into lightweight PQC is

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

ongoing, with algorithms like BIKE, Classic McEliece, and NTRU being evaluated by NIST.

Few studies, however, directly target LoRa's low-resource constraints and long-range communication requirements. Our work differentiates itself by providing a concrete application of code-based cryptography tailored for LoRa's specific architecture.

LoRa Communication Overview. LoRa is a physical layer modulation technique derived from chirp spread spectrum (CSS) technology. LoRaWAN, the corresponding network protocol, adds support for MAC-level management. LoRa supports star topology, operates in unlicensed ISM bands (e.g., 433 MHz, 868 MHz), and typically uses AES-128 for encryption.

Post-quantum cryptography refers to cryptographic algorithms considered secure against both classical and quantum adversaries. The most relevant families include lattice-based, multivariate, hash-based, and code-based schemes.

The Niederreiter cryptosystem is a dual form of the McEliece cryptosystem. It is based on the difficulty of decoding a general linear code. In the Niederreiter scheme:

– Public key: a parity-check matrix of a chosen linear code (e.g., LDPC).

– Private key: transformation matrices and the decoding algorithm for the chosen code.

– Encryption: encode a message as a random error vector and compute its syndrome.

– Decryption: decode the error vector using the private key.

This scheme is known for fast encryption and decryption times and its robustness against quantum attacks.

Low-Density Parity-Check codes are a class of linear error-correcting codes characterized by sparse parity-check matrices. They enable efficient error correction with linear-time encoding and decoding algorithms, such as belief propagation.

With the emergence of quantum computing, classical encryption methods (e.g., RSA, ECC) are becoming susceptible to attacks using Shor's algorithm. This poses a serious threat to secure LoRa-based communication systems, particularly those deployed in sensitive environments such as wildlife tracking, military, or border surveillance.

To future-proof the system, our objective is to integrate post-quantum cryptographic methods that can operate efficiently on constrained hardware such as ESP32 and within the bandwidth limitations of LoRa.

TABLE I. COMPARATIVE ANALYSIS BASED ON THESE FACTORS, NIEDERREITER WITH LDPC CODES IS SELECTED FOR PROTOTYPE IMPLEMENTATION.

Feature	Niederreiter (LDPC)	McEliece (Classic)
Key size	1.3 MB	1.5 MB
Security level	256-bit (quantum-safe)	256-bit
Performance (ESP32)	Moderate (via optimization)	High RAM usage
Code complexity	Medium	High

Our proposed system integrates the Niederreiter encryption scheme into the LoRa communication framework by modifying both the sender (ESP32-based transmitter) and receiver (LoRa gateway or mobile station).

The previously developed mapping system includes the following core elements:

– ESP32 microcontrollers for computation and communication;

– LoRa E32 433T30D modules for long-range communication;

– Offline maps using UTM tiles stored locally on an Android device;

– Real-time location tracking using GPS modules.

Communication protocol for transmitting coordinates and device status via UART over LoRa.

Android application for visualizing map and beacon positions.

Encryption Flow:

– Message preparation: sensor data or GPS location data is prepared;

– Syndrome calculation: data is encoded using the Niederreiter public key;

– Transmission: the encrypted message is transmitted over LoRa.

– Decryption Flow:

– Reception: encrypted message is received;

– Decoding: the syndrome is decoded using the private key (parity-check matrix and decoding algorithm);

– Message reconstruction: original data is recovered and logged.

A test was conducted with the proposed system in an outdoor environment with varying transmission distances (0.5 km – 5 km) and under typical LoRa constraints (SF7-SF12, BW 125 kHz).

Comparative Characteristics of Cryptographic Algorithms.

Table 2 provides a comparative analysis of different cryptographic algorithms in terms of quantum security, key size, and encryption/decryption times. The key findings are:

TABLE II. COMPARATIVE CHARACTERISTICS OF CRYPTOGRAPHIC ALGORITHMS

Algorithm	Quantum Security	Key Size (KB)	Encryption Time	Decryption Time
AES-128	Low	0.016	Very Fast	Very Fast
ECC (256-bit)	Low	0.032	Fast	Fast
NTRU	High	1.2	Medium	Medium
Niederreiter+LDPC	High	0.9	Fast	Fast

– Niederreiter (LDPC) offers a good balance between security and performance, with moderate key size and fast encryption/decryption times on ESP32 hardware. This makes it suitable for LoRa-based systems with constrained resources;

– AES-128 and ECC (256-bit) are fast but offer low quantum security, making them unsuitable for future proofing against quantum attacks;

– NTRU provides high quantum security but has higher key sizes and medium encryption/decryption times, making it less efficient for LoRa's bandwidth constraints;

– The proposed Niederreiter+LDPC combination is highlighted as the optimal choice for integrating post-quantum security into LoRa systems due to its high quantum security, moderate key size, and efficient performance on ESP32.

Despite added cryptographic overhead, the packet delivery ratio (PDR) remained above 95% for distances up to 3 km, dropping to ~85% beyond 4 km in dense urban settings.

Using ESP32 deep sleep between transmissions, the added encryption processing increased average power consumption by ~8%, which remains within acceptable limits for battery-powered applications.

The adoption of Niederreiter encryption with LDPC codes ensures that the system remains secure even against quantum attacks. The security relies on the decoding problem of LDPC codes, which is NP-hard and remains so even with quantum solvers.

The system resists classical attacks (e.g., brute force, replay) and quantum attacks (e.g., Grover's, Shor's algorithms) due to the lack of algebraic structure in the cryptographic primitives used.

Encryption/Decryption Overhead. Table 3 presents the average time and LoRa packet overhead associated with encryption and decryption processes.

Encryption/Decryption Overhead

TABLE III. ENCRYPTION/DECRYPTION OVERHEAD

Operation	Avg Time (ms)	LoRa Packet Overhead (%)
Encryption	3.2	+15%
Decryption	2.7	+15%

The key findings are:

– Encryption and decryption using the Niederreiter scheme add an average overhead of 15% to LoRa packets;

– Despite the added cryptographic overhead, the packet delivery ratio remains high (above 95%) for distances up to 3 km, indicating that the system maintains good performance even with the added security layer;

– The average power consumption increase due to encryption processing is around 8%, which is acceptable for battery-powered applications;

– The decryption time of 2.7 ms and encryption time of 3.2 ms on ESP32 demonstrate that the system can handle cryptographic operations efficiently within the constraints of LoRa communication.

To preserve system performance while introducing cryptographic enhancements, we implemented the following modifications:

– Lightweight cryptographic library for Niederreiter-based key exchange;

– Key compression and fragmentation mechanisms to send large keys over LoRa;

– Use of symmetric encryption (e.g., AES-128 or ChaCha20) for message payloads, with session keys established via post-quantum key exchange;

– Optimized LDPC-based key generation using ESP32's onboard flash and PSRAM.

Post-quantum cryptography can be applied selectively, such as during session initialization, while using symmetric encryption for routine data. This hybrid approach balances security and performance.

Security benefits:

– Quantum-resilient communication channels;

– Immunity to known public-key attacks;

– Suitable for confidential or sensitive field operations.

Performance trade-offs:

– Larger payloads require fragmentation in LoRa, especially with small MTU;

– Key management becomes more complex;

– Requires additional RAM and flash memory usage;

Through testing, we established that the LDPC-based approach provides the best compromise for ESP32-based systems due to:

– Moderate key sizes;

– Lower energy consumption;

– Faster decoding on constrained hardware.

We also implemented a fallback mechanism: if session key exchange fails (e.g., due to poor signal), the system falls back to pre-shared symmetric keys.

To enhance reliability, we introduced CRC validation after each key fragment and retransmission requests. These layers ensure that the key exchange remains robust in challenging RF environments.

Furthermore, application-level safeguards were added to detect and ignore replayed packets using timestamps and nonce values.

TABLE IV. POWER AND BANDWIDTH IMPLICATIOS

Operation	Energy Cost (mJ)	Transmission Time (LoRa, SF12)	Notes
GPS Location (unencrypted)	2.5	250 ms	Single frame
Encrypted (AES-128)	3.2	300 ms	+30% message size
PQ Key Exchange (Niederreiter)	15	2–4 sec (fragmented)	Per session, 1/day or on reconnect
PQ Key Exchange (LDPC)	9	1.5–3 sec (fragmented)	More efficient than Niederreiter

The proposed algorithm enables secure post-quantum key exchange using structured LDPC codes derived from the Niederreiter cryptosystem. We use a binary Goppa or LDPC code with parameters optimized for ESP32 and LoRa constraints.

Fig. 2. Formulas for sparse parity-check matrices

$$H \in \mathbb{F}_2^{(n-k)\times n}$$
$$H_{pub} = P \cdot H$$
$$e \in \mathbb{F}_2^n$$
$$s = H_{pub} \cdot e^T$$
$$K = \mathrm{KDF}(e)$$
$$s' = P^{-1} \cdot s$$
$$\hat{e} = \mathrm{Decode}(H, P^{-1} \cdot s)$$
$$K = \mathrm{KDF}(\hat{e})$$

The LDPC-based key exchange follows a code-based approach similar to Niederreiter but optimized using sparse parity-check matrices

Choose a binary LDPC code with parameters n, k, d where:

– n: code length,
– k: dimension,
– d: minimum distance.

Key Generation (by receiver):

– random permutation matrix P;
– Public Key(H_{pub}), Private Key(H,P).

Encryption (by sender):

– Generate random binary error vector e;
– Compute syndrome s;
– Transmit: syndrome s as ciphertext;
– The shared session key is derived via K, where KDF is a secure Key Derivation Function (e.g., SHAKE256).

Decryption (by receiver):

– Apply inverse permutation s';
– Decode syndrome s' using syndrome decoding to retrieve e;
– Recompute for K.

Power and Bandwidth Implications. Table 4 details the energy cost and transmission time implications of different operations in the system. For constrained LoRa networks, the effective parameters

TABLE V. FOR CONSTRAINED LORA NETWORKS, THE EFFECTIVE PARAMETERS

Parameter	Value
n (code length)	1024
k (dimension)	524
w (error weight)	40
Public Key Size	~2.5 KB
Syndrome Size	500 bits (~63 bytes)
Decoding Time	8–12 ms (ESP32)

The key findings are:

– GPS location transmission without encryption consumes 2.5 mJ and takes 250 ms, while encrypted transmission (using AES-128) increases energy consumption to 3.2 mJ and transmission time to 300 ms, representing a 30% increase in message size;

– Post-quantum key exchange using Niederreiter requires 15 mJ and takes 2-4 seconds per session, while using LDPC reduces the energy cost to 9 mJ and transmission time to 1.5-3 seconds;

– The LDPC-based approach is more efficient in terms of energy and time for post-quantum key exchange, making it a preferred choice for constrained LoRa networks;

– The effective parameters for LDPC (code length, dimension, error weight, public key size, syndrome size, and decoding time) are optimized for ESP32 and LoRa constraints, ensuring that the system remains secure and efficient.

The LDPC decoding is done using the belief propagation algorithm or bit-flipping algorithm, both of which can be implemented efficiently on ESP32.

The hardness of decoding random LDPC codes is equivalent to the Syndrome Decoding Problem (SDP), which is NP-complete and remains resistant even to quantum attacks. Unlike lattice-based systems, the code-based cryptography is not vulnerable to structure-specific quantum attacks such as those targeting NTRU or LWE.

III. CONCLUSION

This work demonstrated how to adapt and extend a previously implemented LoRa mapping system by incorporating post-quantum cryptographic schemes. While preserving the offline map and UTM tile infrastructure, we added strong cryptographic primitives resilient against quantum attacks.

Key findings include:

– LDPC-based cryptographic methods provide an effective trade-off between security, size, and processing requirements;

– Niederreiter encryption remains a viable option where key size is less constrained and security is paramount;

– Session-based key exchange using post-quantum techniques is feasible on ESP32, even under LoRa's strict bandwidth constraints.

Our improvements position the system for long-term deployment in scenarios where data confidentiality, integrity, and resistance to future cryptographic threats are essential.

Future work could explore:

– Hardware acceleration of matrix operations for faster key generation.

– Adaptive encryption schemes based on signal strength and channel capacity.

– Integration with standardized PQC libraries from NIST candidates.

With these enhancements, LoRa-based systems can now operate securely not only in present-day deployments but also in a post-quantum future, ensuring reliable, long-range, and tamper-resistant communication.

***Abstract* — The paper presents a comparative analysis of power losses in electrical distribution networks with different topologies: ring and radial. Using a fragment of a real network scheme with voltage levels of 110, 35, and 10 kV, operating mode calculations were performed under normal conditions and with various line disconnection scenarios. The influence of network configuration on the redistribution of currents and on power losses in lines and transformers is investigated. Based on the obtained results, the technical and economic performance of radial and ring configurations is compared, indicating general conditions for their preferable use. An increase in losses in transformers and lines is identified as a result of current redistribution under certain network configurations. The findings of the study can help improve the efficiency of designing and operating distribution networks.**

Keywords — electrical networks; power losses; radial configurations; ring configurations; current redistribution; network configuration optimization.

I. Introduction

Modern distribution electrical networks impose increasingly high requirements on the efficiency and reliability of power delivery. One of the key factors affecting the operational performance of a network is power loss. The network structure and topology play a decisive role in determining the overall level of losses. In practice, radial and ring distribution schemes are the most widespread. Radial schemes are characterized by simplicity, ease of operation, and relatively low cost. Ring schemes, in turn, provide increased supply reliability due to the possibility of redundancy, but they require more complex control systems and often lead to higher loss levels if the configuration is not optimized properly [1].

The aim of the work is to perform a comparative analysis of power losses under different network configurations based on a real network scheme with three voltage levels — 110 kV, 35 kV, and 10 kV. Special attention is paid to assessing the impact of disconnecting individual lines on the redistribution of currents, voltages and, accordingly, losses in both lines and transformers. Modernized variants of the scheme with modified load parameters and added generation are also considered, which allows a techno-economic evaluation of the efficiency of different configurations. The work is aimed at identifying patterns and formulating recommendations for selecting optimal schemes with minimal power losses and high operational reliability.

II. Materials and Methods

Network Model: The electrical network was modeled using the Python library Pandapower, which is designed for power flow analysis of distribution networks. Pandapower is based on solving power flow equations using the Newton–Raphson method. Initially, the library was created on the basis of PYPOWER, but over time it has been significantly improved in characteristics such as calculation stability, performance, and interface convenience [2]. The network topology and base-case parameters (line types and lengths, transformer ratings, and load levels) replicate the dataset reported in [8]. Building on that dataset, our contribution focuses on comparative loss analysis under ring vs. radial configurations and N−1 line-outage scenarios, with and without distributed generation. In particular, a real distribution scheme with voltage levels of 110, 35, and 10 kV was chosen, encompassing 12 nodes. Fig. 1 shows the one-line diagram of the network, and Fig. 2. shows the equivalent circuit model of the network. The scheme includes overhead transmission lines, power transformers, loads, and power sources. Generation in the system is represented by the slack bus at node 1 (115 kV) and node 2, as well as by generation at the 10 kV buses of node 12. Network parameters, in particular the types of conductors, transformers, and loads, were determined based on reference data and current standards.

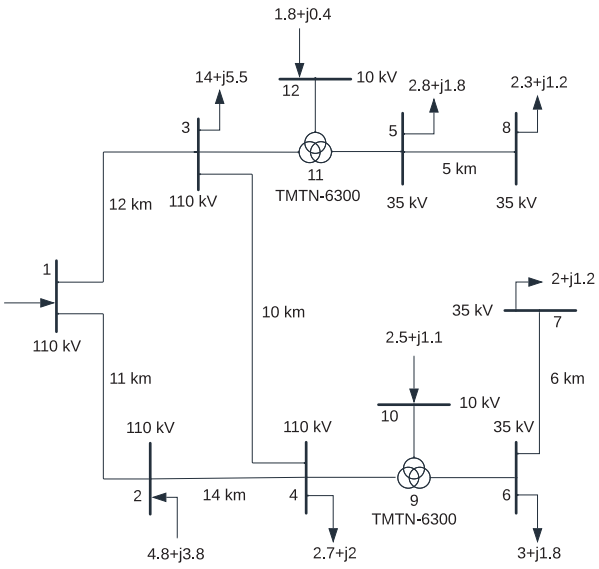

Fig. 1. Diagram of the studied distribution network (110/35/10 kV) — adapted from [8]

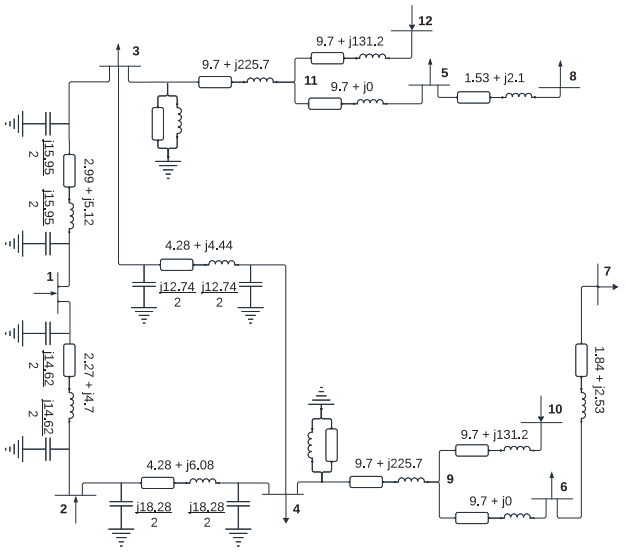

Fig. 2. Equivalent circuit of the electrical network — adapted from [8]

The parameters of the conductors and transformers that form the main sections of the network are presented in Table 1.

TABLE I. PARAMETERS OF NETWORK SECTIONS

Section	Conductor / Transformer Type	l, km / Transformer Winding	r_0, Ohm / km	x_0, Ohm / km	b_0, µS / km	R, Ohm	X, Ohm	B, µS
1-2	AC-120	11	0.249	0.427	2.658	2.74	4.7	29.24
1-3	AC-120	12	0.249	0.427	2.658	2.99	5.12	31.90
2-4	AC-95	14	0.306	0.421	2.611	4.28	6.08	36.55
3-4	AC-70	10	0.428	0.432	2.547	4.28	4.44	25.47
5-8	AC-95	5	0.306	0.421	-	1.53	2.10	-
6-7	AC-95	6	0.306	0.421	-	1.84	2.53	-
3-11	TMTN-6300	HV	-	-	-	9.70	225.7	-
11-5		MV	-	-	-	9.70	0	-
11-12		LV	-	-	-	9.70	131.2	-
4-9	TMTN-6300	HV	-	-	-	9.70	225.7	-
9-6		MV	-	-	-	9.70	0	-
9-10		LV	-	-	-	9.70	131.2	-

"-" denotes a parameter not modeled / not applicable for the given HV/MV/LV segments; shunt susceptance (charging power) is explicitly considered only for the 110-kV lines.

The transformer impedances were calculated based on reference data and converted to per-unit (p.u.), as required by the Pandapower framework. The line elements account for the resistance, reactance, and capacitive characteristics corresponding to their route lengths, and charging power (capacitive reactive power) is also taken into consideration.

One feature of the calculations is the way Pandapower reports reactive power losses: it outputs them as the sum of inductive losses and charging (capacitive) power. For a correct loss analysis, the charging power was calculated separately and then compensated using shunt elements so that inductive losses could be isolated.

Simulation Scenarios: The experimental part of the study was divided into two stages:

• Stage 1 – Base Case and Line Outages: The base configuration of the network was modeled with the given loads and generation (at node 2 and node 12). In this base case, all lines are in service (the ring is closed). Then, N-1 contingency scenarios were simulated by sequentially disconnecting individual lines: 1–2, 1–3, 1–4, 2–4, 3–4, etc. This allowed us to observe how power flow redistribution, voltage changes, and losses in lines and transformers change with each line outage.

• Stage 2 – Effect of Removing Local Generation: The second stage involved analyzing the network with the distributed generation at node 12 disconnected. For each of the line outage scenarios from Stage 1, the power flow calculations were repeated without the local generation. This made it possible to assess the impact of the local generation source on the overall efficiency of the network under each topology scenario.

III. RESULTS AND DISCUSSION

A. Power Losses in the Base Ring Configuration

In the base configuration of the 110/35/10 kV network (all lines in service, ring closed), the total active power losses amount to about 0.31 MW. Of these, losses in the overhead lines are 0.16 MW, and in the power transformers are 0.15 MW. The reactive inductive power losses in the lines of the base scheme are 0.26 MVAr. All these results are summarized in Table 2. At the same time, due to the capacitive currents of the 110 kV lines, the network actually generates reactive power (so-called charging power): in the initial scheme, the 110 kV lines generated about 1.1 MVAr. This proves that we need to consider charging power when analyzing operating modes. The obtained loss values are consistent with standard estimates for distribution networks: greater distance from the power source to the load causes higher energy losses [3]. Reducing these losses is possible by increasing conductor cross-sections, optimizing network topology, and adding generation sources closer to consumers (these approaches are discussed in more detail below).

TABLE II. RESULTS OF POWER LOSS CALCULATIONS FOR THE BASE CLOSED-RING NETWORK.

Voltage level	ΔP, MW in lines	ΔP, MW in transformer windings	ΔQ, MVAr in lines	ΔQ, MVAr in transformer windings
Total	0.161	0.154	0.261	2.073
110 kV	0.145	0.083	0.238	1.940
35 kV	0.017	0.061	0.023	0.000
10 kV	-	0.010	-	0.133

"-" denotes not applicable in this model. The 10-kV level has no explicitly modeled lines; only transformer LV windings are present, hence no 10-kV line-loss entries are reported.

B. Power Losses under Line Outages (Radial Mode)

To analyze the impact of network topology on power loss, N-1 contingency scenarios were examined where individual lines of the ring network are disconnected (specifically lines 1–2, 1–3, 1–4, 2–4, and 3–4). In each such case, the supply to certain network sections had to operate in a radial mode (the ring is opened at the point of outage). It was found that the change in losses depends on which line is disconnected. For example, opening line 1–3 causes node 3 (and partly node 4) to be fed by a longer path via nodes 2 and 4, i.e. through the longer loop 1–2–4–3 instead of the direct 12-km line 1–3. Accordingly, the total path resistance increases significantly, leading to additional energy losses (in this case, losses tripled). In contrast, if line 3–4 is opened, the main nodes 3 and 4 are

still fed directly from node 1 through two parallel branches, and the absence of the 3–4 link has almost no effect on the current distribution (losses increased by only ~2%). Thus, under normal conditions the closed-ring topology yields minimal losses, and switching to a radial mode (opening the ring) increases losses, especially if the break occurs in a main trunk line through which a large portion of the load is fed. These observations reinforce the premise that moving from a radial scheme to a ring scheme can reduce power losses and improve the voltage profile [4]. In our calculations, the ring configuration had ~20–25% lower losses compared to the least optimal radial configuration, and about 2% lower losses compared to the most optimal radial configuration, confirming the benefit of closed topologies for loss reduction. In addition, the closed network demonstrated greater flexibility under fault conditions: in the event of a single contingency, the ring network maintained supply to all nodes (albeit at the cost of some increase in losses due to longer supply paths). Literature also notes that implementing ring schemes improves power supply quality and reliability, especially in the presence of distributed generators [5]. The calculation results for the various line-outage scenarios are summarized in Table 3 and illustrated in Figs. 3, 4, 5.

TABLE III. POWER LOSSES UNDER DIFFERENT NETWORK TOPOLOGY SCENARIOS (SINGLE LINE OUTAGES)

Disconnected line	ΔP, MW in lines	ΔP, MW in transformer windings	ΔQ, MVAr in lines	ΔQ, MVAr in transformer windings
none	0.161	0.154	0.261	2.073
3-4	0.163	0.154	0.266	2.077
1-2	0.189	0.156	0.312	2.095
1-3	0.645	0.163	0.896	2.182
2-4	0.322	0.158	0.513	2.126

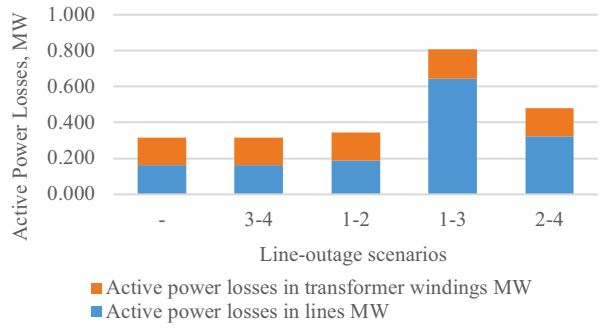

Fig. 3. The total active power losses for different line outage scenarios

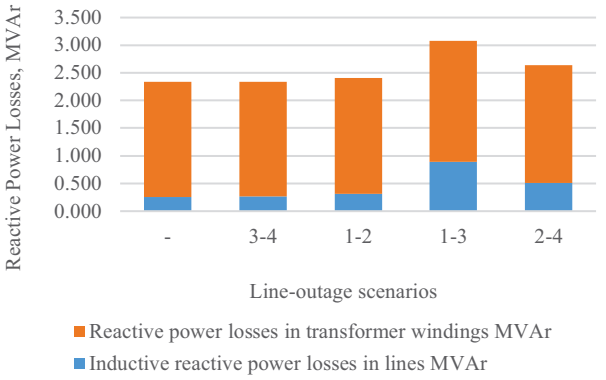

Fig. 4. Ehe total reactive power losses for different line outage scenarios

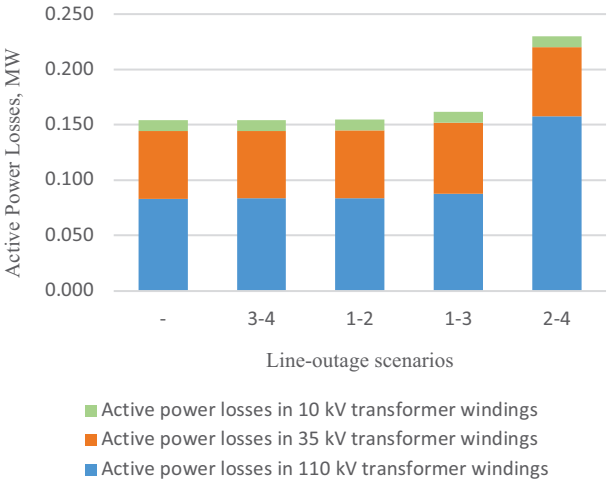

Fig. 5. The active power losses in transformer windings at different voltage levels under each scenario

C. *Effect of Distributed Generation at Node 12*

The introduction of a distributed generation (DG) source at node 12 (on the 10 kV feeder) significantly reduces the power losses in the network. Fig. 6, 7 compare the active power losses for two scenarios: without generation vs. with a 1.8 MW DG connected at node 12.

Fig. 6. Active power losses in lines with and without generation

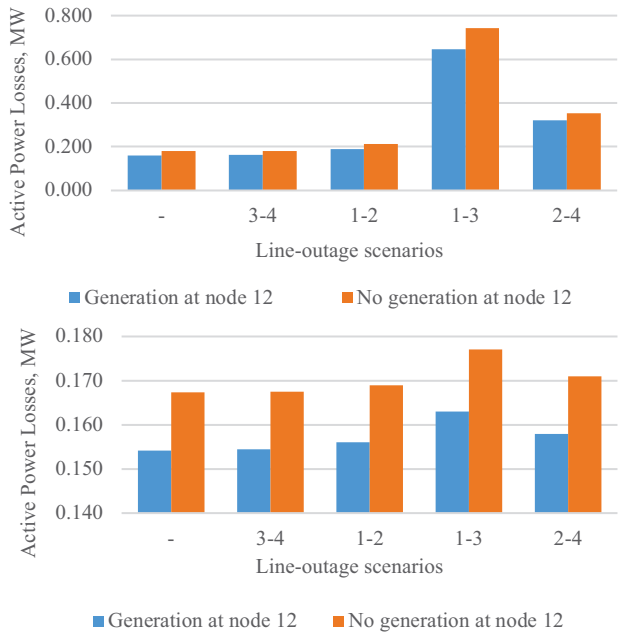

Fig. 7. Active power losses in transformers with and without generation

It can be seen that in steady state (no contingencies), the presence of local generation decreases the active power line losses from ~0.18 MW to ~0.16 MW by partially supplying the load locally, which is consistent with findings of other studies [6, 7]. In contingency cases where lines are disconnected, the effect of the DG varies: if the disconnected line is near the generator, the local source can take on a significant portion of the supply to nodes isolated from the main source, thereby offsetting losses. If the fault occurs far from the generation node, the DG's influence on losses is smaller. Overall, the results support the claim that placing

generation sources closer to consumers offloads the main feeders and improves network efficiency.

D. Ring vs. Radial Topology Optimality

The analysis provides grounds for conclusions regarding the choice of distribution network topology. The ring (closed-loop) configuration demonstrated lower technical losses and greater flexibility under emergency conditions compared to the radial configuration. In normal operation, the presence of parallel paths allows power flows to be split and reduces the loading of each individual line, thus lowering total losses. Under a single contingency, a ring network maintains service to all consumers (each still has at least one supply path), whereas a radial network either requires using backup sources or results in outages or significantly lengthened supply routes, which, as we saw, greatly increases losses. Literature sources note that converting a radial configuration to a ring can reduce losses and improve power supply quality, especially with distributed generation present [5]. Thus, from the perspective of minimizing energy losses, the ring topology is more optimal for this network. At the same time, it should be considered that implementing closed-loop schemes requires more line infrastructure and more complex switching devices, as well as carefully designed protection schemes. Moreover, the efficient operation of such looped systems—especially with integration of renewable energy sources and variable loads—requires ongoing study and improvement of methods to optimize their regimes, for example by voltage regulation to reduce losses [8]. In practice, power distribution often uses compromise approaches: for instance, open rings (normally open at one point, but capable of automatic reconfiguration in case of a fault). This provides near ring-level reliability while operating as radial under normal conditions to avoid circulating currents and simplify control.

Looking ahead, with the increasing share of distributed generation and the development of Smart Grid concepts, one can expect wider adoption of closed-loop and meshed structures, as they better accommodate bidirectional power flows and allow more flexible load sharing while minimizing losses [9]. Our results confirm that with optimal power flow management, a ring topology ensures minimal technical losses and improves network resilience compared to the traditional radial design. Even so, a radial configuration remains technically and economically justified where loads are modest, feeder lengths are short, reliability requirements are moderate, and CAPEX/OPEX constraints apply; in such settings, simpler protection and lower infrastructure costs can outweigh the loss-reduction benefits of ring designs.

CONCLUSIONS

An analysis of power losses in a 110/35/10 kV distribution network under different operating conditions revealed that the ring (looped) configuration has advantages in terms of energy efficiency and reliability. Under normal (no-fault) conditions, the closed topology yields the lowest active and reactive power losses in both lines and transformers. In the event of individual line disconnections, the ring network continues to supply all consumers (each load retains at least one path), whereas a radial network either requires backup sources or leads to outages or significantly longer transmission paths. Therefore, for networks with high reliability requirements and a need for low losses, it is advisable to employ closed (ring or meshed) configurations, provided that the necessary control and protection means are in place. In networks with minor loads or simple distribution schemes, using radial configurations can be justified as a less costly option. It was also found that adding distributed generation to the network significantly reduces losses (by up to ~20%, depending on the scenario) by shortening the energy transmission distance. The results of this work can be used in the design and modernization of distribution power grids to choose the optimal topology from the standpoint of technical losses and reliability.

***Abstract*—The issue of ensuring high energy performance of compensation-type electric energy converters is investigated. It is shown that the use of a new generation of fully controlled devices in the switching link of compensation converters significantly expands the energy capabilities of these means of conversion technology. However, achieving the maximum possible reactive energy generation requires the development and application of certain modes of recharging the capacitors of the commutating link. The result of the conducted research is the determination of regulation modes recommended for practical application.**

Keywords—commutating, control angle electromagnetic process, electric diode, converter, commutating link, control angle

I. Introduction

Developments in the direction of increasing the energy characteristics of electric energy converters have been carried out since the first circuit of such a device was developed. Some researchers use capacitors included in power circuits recharged by industrial frequency currents for this purpose [1, 2]. There are also known circuits of converter units in which capacitors operating at increased voltage and frequency were used to compensate for reactive energy [3]. Despite the abundance of technical solutions, for any compensating converter, the main issue of its operation is the conditions for the formation of the commutating voltage (CV), in other words, the voltage created when recharging the capacitors.

The technological and energy characteristics of the electric energy converter and the efficiency of using its power equipment depend on the magnitude and shape of the CV. In a three-phase bridge compensating converter (circuit, Fig. 1), which is a new technical solution [4], the device intended for the formation of the commutating voltage is the commutating link.

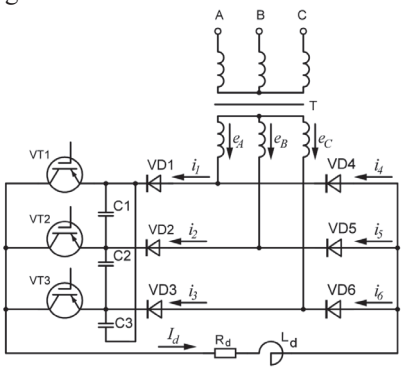

Fig.1.Three-phase bridge compensation converter diagram

It consists of a three-phase capacitor battery (C1, C2, C3) and a three-phase group of IGBT transistors (VT1, VT2, VT3). The three-phase group of transistors provides adjustable recharging of the capacitors, the voltage of which, superimposed on the voltage of the secondary windings of the three-phase converter transformer (T), provides advanced commutating of the current by power electric valves. Such a technical solution is typical for new-generation compensating converters, the development and research of which are in the sphere of interests of the authors of the publication

In the previous generation of compensation converters, the function of the device that provides recharging of the capacitor battery (CB) of the commutating link was performed by a three-phase balancing reactor (TBR). It ensured the passage of the alternating components of the diode currents through the capacitors and the discharge of the constant components of these currents into the external DC circuit, or, in other words, the reactor is an inductive element of the filter that separates the constant and alternating components of the valve currents.

The constant load current I_d is divided by a three-phase balancing reactor into three equal parts. If we neglect the magnetizing current, the reactor phase current $i_R^{(3)}$ will be:

$$i_R^{(3)} = I_R^{(3)} = I_d / 3$$

To prevent forced magnetization of the reactor magnetic circuit by the constant component of the diode currents, six windings are used in it, connected according to the "correct zigzag" scheme.

Information on the technical implementation of the commutating link of the previous generation of compensation converters is intended to use the characteristics of their commutating voltage as a base value when proving the advantages of the new generation of converters.

II. Purpose of Work

To compare the energy capabilities of compensation converters of the previous and new generations and to recommend for practical application those that are capable of providing high energy characteristics and efficient use of equipment.

III. Results of Research

The authors devoted a number of scientific publications to the study of processes in new-generation compensation converters, in particular, to the three-phase bridge

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

compensation converter. In the studies, it was assumed that a three-phase converter transformer (T) creates a standard symmetrical three-phase EMF system of direct phase alternation:

$$e_A = E_m \sin(\vartheta + \pi/6 + \psi);$$
$$e_B = E_m \sin(\vartheta - \pi/2 + \psi); \quad (1)$$
$$e_C = E_m \sin(\vartheta + 5\pi/6 + \psi),$$

where - E_m amplitude of the secondary phase voltage of the converter transformer; ϑ - current variable, ψ - initial voltage phase when the valve is turned on.

First, let us assume that the recharging of the commutating link capacitors is provided by a three-phase balancing reactor. Let us take into account that each valve of the compensation part of the converter (VD1, VD2 and VD3) comes into operation once per period and conducts current for a third of the period. Taking into account the above-described features of the operation of the TBR, in Fig. 2 the current curve of the phase of the capacitor battery C3 is constructed, which takes part in the commutating of the current from the valve VD3 to VD1.

As we can see, this current has three intervals in the period, each with a length of . The magnitude of the current at individual intervals: I – $i_c = -I_d/3$; II – $i_c = 0$; III – $i_c = I_d/3$.

Analytical calculation of the commutating voltage curve u_C by intervals is carried out using the form of the capacitor phase current according to the following relationship:

$$u_C = \frac{1}{\omega C}\int_0^{\vartheta} i_C d\vartheta + u_C(0). \quad (2)$$

The number of intervals of the commutating voltage curve is the same as the number of intervals of the current curve:

$$\text{I - } u_{C(1)} = \frac{1}{\omega C}\int_0^{\vartheta}(-\frac{I_d}{3})d\vartheta + u_C(0) = -\frac{I_d}{3\omega C}\vartheta + u_C(0).$$

$$\text{II - } u_{C(2)} = \frac{1}{\omega C}\int_0^{\vartheta} i_C d\vartheta + u_{C(1)k} = -\frac{2\pi I_d}{9\omega C} + u_C(0) = u_{C(2)k}.$$

$$\text{III - } u_{C(3)} = \frac{1}{\omega C}\int_0^{\vartheta}\frac{I_d}{3}d\vartheta + u_{C(2)k} = \frac{I_d}{3\omega C}\vartheta - \frac{2\pi I_d}{9\omega C} + u_C(0).$$

According to the calculation performed, in Fig. 2 the commutating voltage curve was constructed $u_C(\vartheta)$ and its initial value, which is also its maximum value, was calculated:

$$u_C(0) = \frac{I_d}{3\omega C}\cdot\frac{4\pi}{9} = \frac{2I_d}{27fC} \quad (3)$$

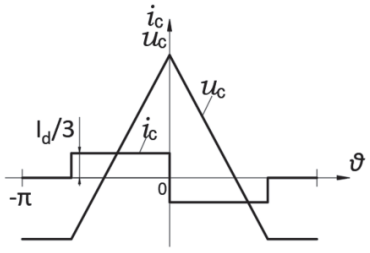

Fig.2. Commutating voltage and current curves of phase C3 of the capacitor battery

Analytical calculation of the commutating voltage curve by intervals is carried out using the form of the capacitor phase current according to the following relationship:

The disadvantage of the previous generation of compensation converters is the use of a three-phase balancing reactor in the switching link. Not only is it a bulky element with large energy losses. It is a passive element that is unable to regulate the process of recharging the capacitor battery.

The use of a new generation of fully controlled devices (IGBTs) in the switching link of compensation converters makes the process of recharging capacitors controllable. In other words, it becomes possible to regulate the commutating voltage both in form and in magnitude. The magnitude and form of the commutating voltage are influenced by factors such as the moment of inclusion in the operation of fully controlled devices of the commutating link, the frequency of control pulses and the adjustment range. The combination of these factors in different modes of operation of the converter is ultimately expressed in different energy capacities. Their study is a serious scientific task, since its solution will allow to formulate recommendations for ensuring effective operating modes of the studied converter, which corresponds to the purpose of the current publication.

When studying the influence of a set of factors on the formation of the commutating voltage, the following priority was adopted: the frequency of the control pulses of the commutating link transistors, the moment of switching on the transistors and the adjustment range. It was also taken into account that the magnitude of the commutating voltage depends on the capacitance of the phase CB of the commutating link and the magnitude of the load current, which, in turn, depends on the voltage of the secondary winding of the converter transformer and the load resistance of the converter. Also, in all studies, the moment of entry into operation of the diode VD1 of phase A when the current passes from the diode VD3 to the diode VD1 was taken as the starting point. For an objective comparison of the results of the studies in different operating modes of the converter, these values were taken to be the same, namely:

$U_{m2} = 57.8$ (*V*), $C = 0.000065$ (*F*), $R_d = 37.5$ (*Ohm*). (4)

If, based on the given data, we calculate for (3) the maximum value of the commutating voltage in the compensation converter of the previous generation (with TBR) - it turns out 50.14 (*V*). Here it is taken into account that for data (4) the rectified current of the converter is 2.2 (*A*).

Data (4) are also technical characteristics of the circuit model used in the current scientific research.

Let the transistors of the commutating link be controlled by pulses of a single frequency, i.e. a frequency corresponding to the frequency of the power supply network. It corresponds to a three-phase system of voltages of direct phase sequence. Accordingly, the transistors of the commutating link operate in the sequence VT1 → VT2 → VT3.

If the moment of switching on the transistor VT1 coincides with the moment of switching on the power electric diode VD1, the current through the capacitors of the commutating link does not pass, the commutating voltage is zero. That is, the converter will operate in the normal (non-compensated) mode. If the moment of applying the control pulse is applied to the transistors with some delay (θ), this will create conditions for the passage of current through the

phases of the CB. As a result of its charge in the electromagnetic process of the converter, an additional voltage will appear, which is called the commutating voltage. In this case, the converter switches to the compensated mode of operation.

Mode 1. Consider the first control range, in which the delay of control pulse supply to the transistors of the commutating link is within $0 \le \theta \le 2\pi/3$. The dynamics of changes in the magnitude and shape of the phase current of the capacitor battery is quite simple - the greater the delay of the control pulse supply (θ), the greater the length of the current through the phases of the CB. Just the length. The magnitude of the current remains unchanged. The current of the CB phase in the period has six intervals, which is presented in Fig. 3, *a*.

Replacing a three-phase balanced reactor with a three-phase group of fully controlled devices is a purely technical solution. Similar solutions are used in the creation of capacitive commutated converters both abroad [1, 3] and in our country [2, 5]. It would seem that the recharging of the capacitors of the commutating link should occur similarly to the previous generation converters with TBR. Comparing Figures 2 and 3, we see that this is not at all the case. The reason for this is that the TBR divides the rectified current of the converter into three equal parts and the current through the TBR phase flows constantly during the period. In other words, the instantaneous and average values of the current in the TBR phase are the same and equal to a third of the rectified current.

When controlling the transistors of the commutating link with single-frequency pulses, the situation with the CB overcharging is completely different. The entire rectified current of the converter passes through each IGBT during a third of the period. The other two thirds of the period there is no current through the transistor. Therefore, the average value of the transistor current is equal to a third of the rectified current of the converter, and the instantaneous one is not.

The commutating voltage is calculated by the relation (2). Like the current, its curve over the period has six intervals. Let $\theta=\pi/3$. Based on the algorithm of current commutating by power electric valves and the moment of commutating on the transistors of the commutating link, the length of each interval will be equal to $\pi/3$. And the pattern of change at individual intervals will be as follows:

$$\text{I - } u_{C(1)} = \frac{1}{\omega C}\int_0^{\vartheta}(-\frac{2I_d}{3})d\vartheta + u_C(0) = -\frac{2I_d}{3\omega C}\vartheta + u_C(0).$$

$$\text{II - } u_{C(2)} = \frac{1}{\omega C}\int_0^{\vartheta} i_C d\vartheta + u_{C(1)k} = -\frac{I_d}{9fC} + u_C(0) = u_{C(2)k}.$$

$$\text{III - } u_{C(3)} = \frac{1}{\omega C}\int_0^{\vartheta}(\frac{I_d}{3})d\vartheta + u_{C(2)k} = \frac{I_d}{3\omega C}\vartheta - \frac{I_d}{9fC} + u_C(0).$$

$$\text{IV - } u_{C(4)} = \frac{1}{\omega C}\int_0^{\vartheta} i_C d\vartheta + u_{C(3)k} = -\frac{I_d}{18fC} + u_C(0) = u_{C(4)k}.$$

$$\text{V - } u_{C(5)} = \frac{1}{\omega C}\int_0^{\vartheta}\frac{I_d}{3}d\vartheta + u_{C(4)k} = \frac{I_d}{3\omega C}\vartheta - \frac{I_d}{18fC} + u_C(0).$$

$$\text{VI - } u_{C(6)} = \frac{1}{\omega C}\int_0^{\vartheta} i_C d\vartheta + u_{C(5)k} = u_C(0).$$

Assuming that the average value of the curve $u_c(\vartheta)$ over the period is zero, we obtain:

$$u_C(0) = \frac{I_d}{18fC}\ . \tag{5}$$

The result corresponds to the case $\theta=\pi/3$. If we extend it to the entire regulation range in mode 1, we obtain:

$$u_C(\vartheta) = \frac{I_d}{3\omega C}\cdot\theta \tag{6}$$

Considering that the largest value of the switching voltage falls on $\theta = 2\pi/3$, the ratio for its calculation will be as follows:

$$U_{C\max} = I_d / 9fC\ . \tag{7}$$

Taking into account data (4) and the fact that with a larger value of the leading angle of regulation, the rectified voltage and rectified current will be somewhat smaller (in the case under consideration $I_d = 2.05(A)$), at the end of the regulation range the numerical value of the switching voltage is $U_{C\max} \approx 70(V)$. This value is 1.4 times greater than that obtained under the same conditions for the previous generation converter.

The regularity of the change in the switching voltage curve in mode 1 over intervals over the period of the power supply frequency is generalized, we write it as follows:

I $u_{CI}(\vartheta) = U_{mC}(1-\frac{2}{\theta}\vartheta),\quad 0 \le \vartheta \le \theta$;

II $u_{CII}(\vartheta) = -U_{mC},\quad \theta \le \vartheta \le 2\pi/3$;

III $u_{CIII}(\vartheta) = U_{mC}(\frac{1}{\theta}\vartheta - \frac{2\pi}{3\theta} - 1),\quad 2\pi/3 \le \vartheta \le (2\pi/3+\theta)$;

IV $u_{CIV}(\vartheta) = 0,\quad (2\pi/3+\theta) \le \vartheta \le 4\pi/3$;

V $u_{CV}(\vartheta) = U_{mC}(\frac{1}{\theta}\vartheta - \frac{4\pi}{3\theta}),\quad 4\pi/3 \le \vartheta \le (4\pi/3+\theta)$;

VI $u_{CVI}(\vartheta) = U_{mC},\quad (4\pi/3+\theta) \le \vartheta \le 2\pi$.

According to the above equations, Fig. 3, *b* illustrates the dynamics of changes in the magnitude and shape of the commutating voltage when the moment of entry into operation of the transistor VT1 changes in the range $0 \le \theta \le 2\pi/3$.

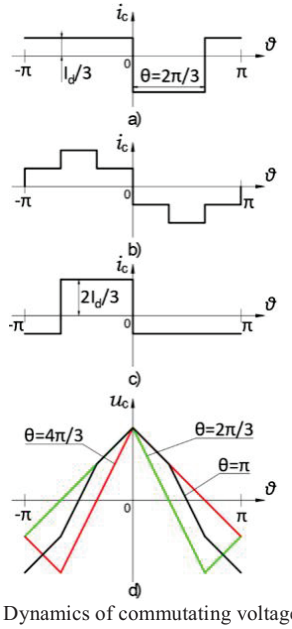

Fig.3. Dynamics of commutating voltage change in mode 1

The compensatory mode of operation of the converter is achieved by introducing an additional voltage into the commutating circuit, which is the commutating voltage. Superimposed on the linear voltage of the secondary winding of the converter transformer, it creates conditions for the leading current switching by power electric diodes [6]. The fact of superposition makes important not only the magnitude of the commutating voltage, but also its shape. Therefore, the conclusion regarding the 1.4 times greater magnitude of the commutating voltage should not be perceived as a great advantage of the operation of the new generation compensatory converter in mode 1. The advantage of the converter operation in the specified mode is precisely the possibility of smooth adjustment of the magnitude of the commutating voltage. But this value is limited by the transition of the converter to another operating mode.

Mode 2. Theoretically, the converter operation in mode 1 will continue until the delay of switching on the transistor VT1 reaches the value $\theta = 2\pi/3$, which is the boundary between modes 1 and 2. With an increase in the delay of switching on the transistor of the commutating link, the phase current of the capacitor battery will change in shape and will not change in magnitude. The period will have six intervals. The dynamics of the change in the shape of the current of the phase C3 CB of the commutating link at different moments of control pulse supply is shown in Fig. 4,*a*.

Let us calculate, using (2), the shape of the switching voltage at a delay $\theta = \pi$, or $\theta = \pi/3$, counting it from the beginning of the start of operation of the power electric valve VD2 of phase B of the converter:

$$\text{I } u_{C(1)} = \frac{1}{\omega C}\int_0^{\vartheta}(-\frac{I_d}{3})d\vartheta + u_C(0) = -\frac{I_d}{3\omega C}\vartheta + u_C(0).$$

$$\text{II } u_{C(2)} = \frac{1}{\omega C}\int_0^{\vartheta}(-\frac{2I_d}{3})d\vartheta + u_{C(1)k} = -\frac{2I_d}{3\omega C}\vartheta - \frac{I_d}{18fC} + u_C(0).$$

$$\text{III } u_{C(3)} = \frac{1}{\omega C}\int_0^{\vartheta}(-\frac{I_d}{3})d\vartheta + u_{C(2)k} = -\frac{I_d}{3\omega C}\vartheta - \frac{I_d}{6fC} + u_C(0).$$

$$\text{IV } u_{C(4)} = \frac{1}{\omega C}\int_0^{\vartheta}\frac{I_d}{3}d\vartheta + u_{C(3)k} = \frac{I_d}{3\omega C}\vartheta - \frac{2I_d}{9fC} + u_C(0).$$

$$\text{V } u_{C(5)} = \frac{1}{\omega C}\int_0^{\vartheta}\frac{2I_d}{3}d\vartheta + u_{C(4)k} = \frac{2I_d}{3\omega C}\vartheta - \frac{I_d}{6fC} + u_C(0).$$

$$\text{VI } u_{C(6)} = \frac{1}{\omega C}\int_0^{\vartheta}\frac{I_d}{3}d\vartheta + u_{C(5)k} = \frac{I_d}{3\omega C}\vartheta - \frac{I_d}{18fC} + u_C(0).$$

The initial value of the commutating voltage curve $u_C(0)$, which is also its maximum value, is calculated based on the fact that the average value of the curve $u_C(\vartheta)$ over the period is zero.

Having performed the calculation, we obtain:

$$u_C(0) = \mathrm{U}_{C\max} = I_d / 9fC. \qquad (8)$$

The general pattern of the change $u_C(\vartheta)$ in the frequency of the power supply network over the period is written as follows:

$$\text{I } u_{CI}(\vartheta) = U_{mC}(1 - \frac{3}{2\pi}\vartheta), \quad 0 \le \vartheta \le \theta;$$

$$\text{II } u_{CII}(\vartheta) = U_{mC}(1 + \theta_* - \frac{3}{\pi}\theta), \quad \theta \le \vartheta \le 2\pi/3;$$

$$\text{III } u_{CIII}(\vartheta) = U_{mC}(\theta_* - \frac{3}{2\pi}\vartheta), \quad 2\pi/3 \le \vartheta \le (2\pi/3 + \theta);$$

$$\text{IV } u_{CIV}(\vartheta) = U_{mC}(\frac{3}{2\pi}\vartheta - 2 - \theta_*), \quad (2\pi/3 + \theta) \le \vartheta \le 4\pi/3;$$

$$\text{V } u_{CV}(\vartheta) = U_{mC}(\frac{3}{\pi}\vartheta - 4 - \theta_*), \quad 4\pi/3 \le \vartheta \le (4\pi/3 + \theta);$$

$$\text{VI } u_{CVI}(\vartheta) = U_{mC}(\frac{3}{2\pi}\vartheta - 2), \quad (4\pi/3 + \theta) \le \vartheta \le 2\pi.$$

In the above expressions, the normalized value is $\theta_* = \theta/(2\pi/3)$. The dynamics of changes in the magnitude and shape of the switching voltage when the moment of entry into operation of the transistor VT1 in the range $2\pi/3 \le \theta \le 4\pi/3$ is illustrated in Fig. 4,*b*.

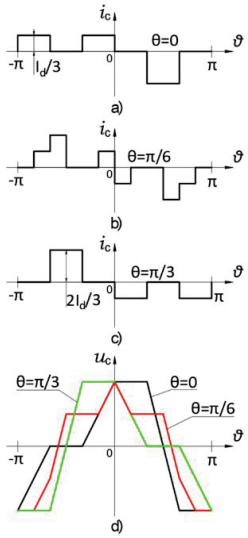

Fig.4. Dynamics of commutating voltage change in mode 2

The main feature of the converter operation in mode 2 is that throughout the entire regulation range the maximum value of the commutating voltage curve does not change. It is shape changes. Moreover, in such a way that it is possible to provide the maximum possible value of the switching voltage without restrictions caused by the operating mode. Let us illustrate the results of the circuit modeling in the Micro-Cap 12 package. The circuit model of the three-phase bridge compensation converter is shown in Fig. 5. The parameters of the model elements correspond to (4).

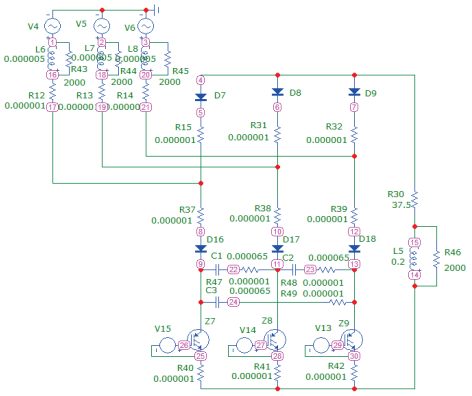

Fig.5. Object-oriented model of a three-phase bridge compensation converter

Formally, the operation of the converter when regulating the commutating link according to mode 2, with respect to the magnitude of the leading control angle, is the same, since the magnitude of the commutating voltage does not change. If we also take into account the possibility of an additional increase in the magnitude of the commutating voltage by reducing the capacitance of the phase of the capacitor battery, the situation does not look so unambiguous. According to this indicator, the beginning of the regulation process in mode 2 is the least productive. This can be seen from the modeling results shown in Fig. 6, *a*. Imposition the commutating voltage curve on the linear voltage curve of the secondary winding of the converter transformer leads to the transition of the converter to another operating mode, which in the theory of compensation converters is called the re-operation mode. Such an operating mode is undesirable due to the poorer energy performance and operating conditions of power equipment [7].

Increasing the delay moment improves θ the energy capabilities of the converter. This is confirmed by the results of circuit modeling shown in Fig. 6, *b* and *c*. They correspond to $\theta = \pi$ and show the possibility of obtaining the maximum possible amounts of reactive power generation, which are limited not by the insufficient value of the commutating voltage, but by the superposition of the current of the power electric valves of the cathode group on the valve of the anode group (Fig. 6, *c*). So far, this is the best indicator of the energy capabilities of the converter and it was obtained when the capacitance of the phase CB of the commutating link is half the base one given in (4), i.e. $0.0000325(F)$. Compared with the base mode, the efficiency of capacitors use is 2.

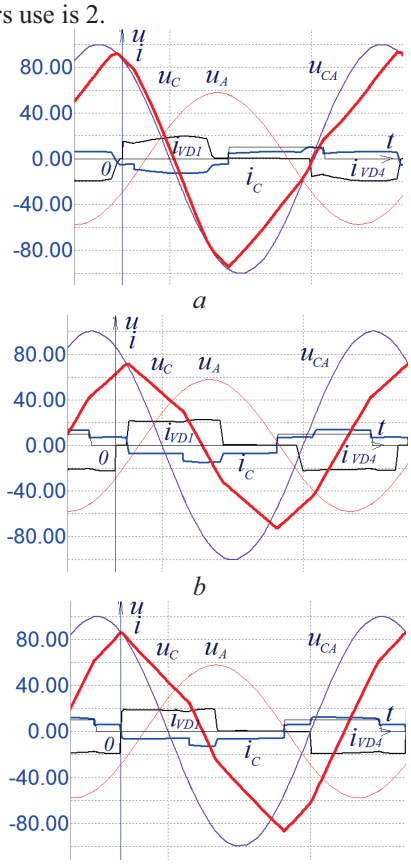

Fig.6. Results of simulation of the operation of the converter in mode 2

Mode 3. Let us increase the frequency of pulse supply to the transistors of the commutating link to double. Let $\theta = 0$, based on the algorithm of current commutating by power electric diodes and the moment of commutating on of the transistors of the commutating link, the phase current of the capacitor battery during the period has 6 intervals with different patterns of change. Accordingly, the commutating voltage during the period will have the same number of intervals. Its calculation according to the relation (2) gives the following result:

$$\text{I - } u_{C(1)} = \frac{1}{\omega C}\int_0^{\vartheta} i_C d\vartheta + u_C(0) = u_C(0) = u_{C(1)k}.$$

$$\text{II - } u_{C(2)} = \frac{1}{\omega C}\int_0^{\vartheta} (-\frac{2I_d}{3}) d\vartheta + u_{C(1)k} = -\frac{2I_d}{3\omega C}\vartheta + u_C(0).$$

$$\text{III - } u_{C(3)} = \frac{1}{\omega C}\int_0^{\vartheta} i_C d\vartheta + u_{C(2)k} = -\frac{I_d}{9fC} + u_C(0) = u_{C(3)k}.$$

$$\text{IV - } u_{C(4)} = \frac{1}{\omega C}\int_0^{\vartheta} (\frac{I_d}{3}) d\vartheta + u_{C(3)k} = \frac{I_d}{3\omega C}\vartheta - \frac{I_d}{9fC} + u_C(0).$$

$$\text{V - } u_{C(5)} = \frac{1}{\omega C}\int_0^{\vartheta} i_C d\vartheta + u_{C(4)k} = -\frac{I_d}{18fC} + u_C(0) = u_{C(5)k}.$$

$$\text{VI - } u_{C(6)} = \frac{1}{\omega C}\int_0^{\vartheta} \frac{I_d}{3} d\vartheta + u_{C(5)k} = \frac{I_d}{3\omega C}\vartheta - \frac{I_d}{18fC} + u_C(0).$$

The initial value of the commutating voltage curve $u_C(0)$, which is also its maximum value, is calculated based on the fact that the average value of the curve $u_C(\vartheta)$ over the period is zero. Having performed the calculation, we obtain:

$$u_C(0) = U_{C\max} = I_d / 18fC. \qquad (9)$$

Having performed a numerical calculation of the maximum value of the commutating voltage according to the relation (9) using the data (4), we obtain $U_{C\max} = 39.14(V)$, which is confirmed by Fig. 7, *a*.

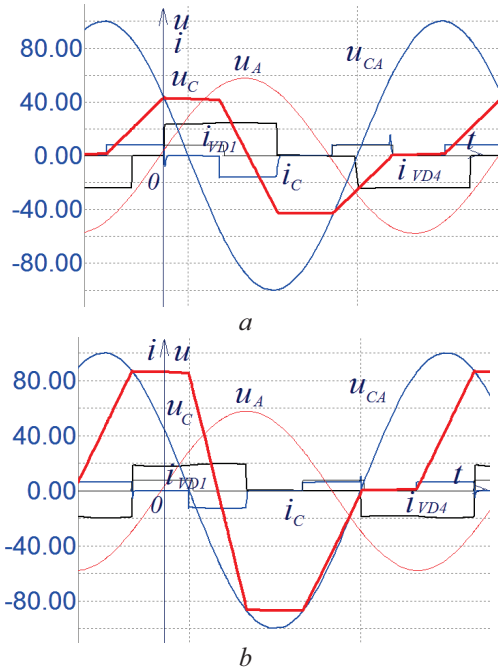

Fig.7.Results of simulation of converter operation in mode 3

Accordingly, Fig. 7, *b*, which is also the result of the circuit simulation of the studied mode, illustrates the possibility of the converter achieving the maximum commutating voltage. That is, achieving such an operating mode when the increase in the commutating voltage is limited by the superposition of the current of the power electric diodes of the cathode group on the diodes of the anode group. Such a mode was achieved in mode 2. But in mode 3, the efficiency of using the capacitors of the commutating link is higher, since this occurs at a capacitor phase capacitance of 0.000025 (*F*). Compared with the base mode, the efficiency of using the capacitors is 2.6.

Within the framework of one publication, it is not possible to present in detail the results of research on the specified topic at different frequencies of control pulses of the transistors of the commutating link. Therefore, we will limit ourselves to information on the results obtained from other studies.

At an eight-fold frequency of control pulses, it is possible to achieve the same performance as in mode 2. The efficiency of using the capacitors of the commutating link will be the same. Further increase in this frequency does not lead to an increase in the efficiency of the operating modes.

The reason for this is explained by Fig. 8. It presents the results of circuit modeling at a 32-fold frequency of control pulses of the commutating link transistors. As we can see, the switching voltage curve in shape and magnitude approaches that shown in Fig. 2. Recall that this voltage was such in the compensation converters of the previous generation, when the rectified current of the converter passed through all the phases of the TBR throughout the time.

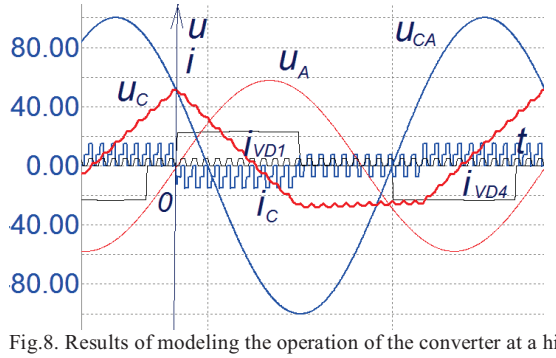

Fig.8. Results of modeling the operation of the converter at a high frequency of control pulses

Replacing the three-phase balancing reactor with a three-phase group of fully controlled devices is in itself a step forward in technical and economic terms, as discussed at the beginning of the publication. At the same time, the nature of the movement of the components of the rectified current through the transistors of the commutating link also changed. This process was most uneven in time at a single frequency of control pulses. The current passed through the transistor for a third of the period once per period. As the frequency of control pulses increased, the unevenness in the time of the current passing through the transistors of the commutating link was leveled out. And the shape of the commutating voltage approached that which was in the converters of the previous generation.

IV. CONCLUSIONS

1. The quantitative indicator of the possible volumes of reactive energy generation by the studied compensating converter is the value of the leading angle of regulation of the electric power valves of its compensative part. The value of the leading angle of regulation directly depends on the value of the commutating voltage. The paper shows how to organize the recharging of the commutating link capacitors in order to prevent the occurrence of situations in which the growth of the commutating voltage is blocked.

2. Based on the indicator of the possibility of achieving the maximum value of the leading angle of regulation of the power electric valves of the three-phase bridge compensative converter, and, accordingly, the generation of maximum volumes of reactive energy with the efficient use of the commutating link capacitors, the paper defines the control modes of the commutating link capacitors that are promising for practical application. It is proven that achieving high energy characteristics is based on the coordination of the following factors: the moment of switching on the fully controlled devices of the commutating link, the frequency of the control pulses of the commutating link transistors and the control range.

3. Object-oriented modeling of the operating modes of the studied electric energy converter, on the one hand, confirmed the results of theoretical studies, and on the other hand, was used as an independent research device. The modeling results showed the feasibility of limiting the frequency of control pulses to the transistors of the commutating link and showed how and to what extent it is possible to increase the efficiency of using a capacitor battery compared to the basic mode.

***Abstract*—Conventional coal tar dewatering methods—gravity settling, thermal treatments, and centrifugation—are inefficient due to high costs and poor performance in treating dense, viscous emulsions. Emerging multiphysics-assisted techniques (e.g., electric fields, ultrasonics) outperform traditional approaches by enhancing droplet coalescence and emulsion destabilization with lower energy use. However, coal tar's physicochemical complexity—compositional heterogeneity, variable dielectric behavior (ε=2.5–3.5), and non-Newtonian viscosity—impedes field interactions, destabilizes coalescence kinetics, and compromises system scalability. Electrostatic dewatering, for instance, is constrained by insufficient polarization contrast with water (ε ≈ 78), reducing droplet coalescence efficiency. Conductive quinoline-insoluble (QI) aggregates further disrupt electric fields, causing short circuits and localized discharges, while pyrolysis-derived tars elevate viscosity, hindering droplet mobility. Modeling shows dehydrator efficiency declines sharply with coal tar density increases (1165–1200 kg/m³), requiring coalesced droplets ≥200 µm for viable separation. To address these challenges, system designs must adapt to coal tar's dielectric variability, QI content, and rheology. Key operational parameters—temperature, electric field strength, and droplet dynamics—require optimization to balance coalescence rates and energy consumption. Successful implementation hinges on mitigating coal tar's inherent variability through tailored engineering solutions, ensuring robust dewatering performance despite fluctuating feedstock properties. This integrated approach could enable scalable, energy-efficient moisture removal, overcoming limitations of legacy methods in meeting industrial standards.**

Keywords—coal tar, dehydration, dielectric properties, quinoline insoluble substances.

I. Introduction

In the coke industry, conventional coal tar dewatering relies primarily on gravitational separation, wherein the material is retained in heated storage tanks at 80–90 °C for prolonged durations, often exceeding 36 hours. Secondary dewatering is then accomplished either via centrifugal separation (using industrial centrifuges) or thermal treatment in tubular furnaces. In the thermal process, coal tar is preheated to approximately 130 °C in the convection section before undergoing evaporation in a primary unit, where moisture content is reduced to below 0.5%.

These traditional methods exhibit several limitations, including high energy consumption, extensive equipment requirements, and significant spatial demands. Additionally, their efficiency is constrained by persistent challenges at the air–water–tar interface, where corrosive effects are pronounced. Separation of water from high-viscosity, dense coal tar proves particularly problematic, often failing to achieve the industrial specification of <4% mass moisture content.

In contrast, electrostatic dewatering enables rapid and efficient separation of dispersed water droplets from coal tar through the application of strong polarization and dielectrophoretic forces at the oil–water interface. This method substantially reduces energy consumption and equipment footprint compared to conventional thermal or centrifugal approaches, as it operates effectively at lower temperatures and without complex mechanical systems. Moreover, electric field treatment demonstrates superior performance for high-viscosity, dense coal tar emulsions, promoting droplet coalescence and sedimentation where gravity-based methods are inadequate.

An early innovation in electro-assisted separation is detailed in [1], which discloses a coal tar dewatering apparatus utilizing a high-voltage electric field. The device exploits the significant dielectric contrast between coal tar and water, inducing polarization of dispersed water droplets and enhancing their coalescence and settling. This approach offers distinct advantages, including reduced thermal energy input and improved separation efficiency—particularly for stable emulsions resistant to gravitational dewatering. The design emphasizes optimized electrode configuration and robust insulation, ensuring operational safety under high-voltage conditions.

Patent [2] describes a hybrid dehydrator designed for heavy oil and coal tar, integrating mechanical separation with electric field enhancement. The system employs a multi-stage

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

process where gravitational settling is augmented by an applied electric field, significantly accelerating phase separation. Key design features include optimized flow paths to maximize residence time in the electrostatic zone and a modular configuration for scalable operation. This hybrid approach demonstrates superior performance compared to purely thermal methods, with enhanced adaptability to varying feedstock viscosities and moisture content.

A notable advancement in hybrid separation technology is presented in [3], which combines ultrasonic and electric field treatments for coal tar dewatering. The process begins with ultrasonic irradiation to destabilize emulsions by disrupting interfacial films and inducing droplet coalescence. Subsequent electrostatic treatment enhances the aggregation and separation of polarized water droplets. The synergistic effect of ultrasonic cavitation and dielectrophoresis markedly improves dewatering kinetics and reduces residual water content, even in high-viscosity or resin-rich tar fractions. This dual-field strategy is particularly effective for complex emulsions that resist conventional separation methods.

Patent [4] proposes a specialized method and apparatus for dewatering high-temperature coal tar, leveraging elevated temperatures (130–150 °C) to reduce viscosity and facilitate water separation. The system integrates preheated convection zones with evaporative separation chambers, employing controlled heating profiles and heat recovery mechanisms to optimize energy efficiency. While this thermal-mechanical approach consumes more energy than electrostatic methods, it maintains tar quality and is well-suited for industrial applications where waste heat from upstream processes can be utilized.

A clear trend across these patents is the shift toward multiphysics-assisted separation, where electric fields—often combined with ultrasonic energy—supplement or replace conventional thermal and gravitational methods. Electric fields enhance droplet coalescence by leveraging the dielectric contrast between water and tar, while ultrasonic irradiation promotes emulsion destabilization through cavitation-induced interfacial disruption. Compared to traditional techniques, these hybrid approaches demonstrate superior dewatering efficiency, reduced processing times, and lower energy consumption—particularly for viscous and highly emulsified coal tar fractions.

Despite promising laboratory-scale results and innovative conceptual designs, industrial adoption of electro-assisted and hybrid dewatering technologies remains limited. Key barriers include unresolved scientific and engineering challenges, primarily stemming from the complex and variable physicochemical properties of coal tar. These inherent material characteristics critically influence the performance and operational stability of electric and ultrasonic dewatering systems, posing significant hurdles for large-scale implementation.

The aim of this study was to evaluate the efficiency and throughput of a standard electrodehydrator for coal tar with different degrees of pyrolisation. The nature of substances insoluble in quinoline as a significant factor influencing the dehydration process was taken into account.

II. Materials and Methods

The morphological composition of solid tar inclusions (components insoluble in quinoline) and the distribution of water droplets in water-in-resin reverse emulsion for the studied resins were determined using a Neofot optical microscope equipped with a ToupTech attachment and ToupView software. The particle size distribution of the same insoluble substances was determined using a Jeol JSM 840 high-precision scanning electron microscope. Dielectric properties of the constituent morphological particles insoluble in quinoline were obtained from the data presented in publications [5-7]. The rheological characteristics of the studied liquids were determined by a Brookfield LV DV2T rotational viscometer (low viscosity digital viscometer) with a thermal cell

In the framework of this work, coal tar of different pyrolisation degrees, characterised by approximately the same water content (10-12 %), were analysed. The detailed characterisation of the investigated resins is presented in Table 1.

TABLE I. Characterisation Of Investigated Tars With Different Degrees Of Pyrolysis

Density 20°C, kg/m³	**Mass fraction, % of insoluble in**		**Elemental composition, %**				
	toluene	***quinoline***	***C***	***H***	***N***	***O***	***S***

1175	8.4	4.2	89.50	5.61	0.43	4.11	0.35
1200	17.3	12.2	90.40	5.06	0.50	3.69	0.35

To assess the applicability of the technology of electrostatic dehydration of tar with different degrees of pyrolization, we used the calculation method of the 2EG-160-2 electrostatic dehydrator for the “oil-water” system.

The formula for calculating the performance of the electrohydrator is essentially a modification of the Stokes equation adapted for vertical deposition of water droplets in the oil flow inside a cylindrical apparatus [8]:

$$G=\frac{L\times D\times g\times d^2(\rho_{tar}-\rho_w)}{72\times\nu_{tar}\times\rho_{tar}} \qquad (1),$$

where: G - productivity of the apparatus on raw material, m^3/s; L - length of the apparatus, m; D - inner diameter of the apparatus; g - acceleration of free fall, m/s^2; d - diameter of the floating drop, m; ρ_{tar} - density of tar, kg/m^3; ρ_w - density of water, kg/m^3; ν_{tar} - kinematic viscosity of tar, m^2/s; 1/72 - empirical coefficient that takes into account the units of measurement and the transition from droplet deposition to mass productivity (m^3/s).

III. Result And Discussion

The morphological composition of quinoline-insoluble substances, isolated from coal tars with varying degrees of pyrolysis, along with the water droplet diameter in "water-in-tar" emulsions, are presented in Table 2. Representative photomicrographs of the hydrated tar are shown in Figures 1, while photomicrographs of the quinoline-insoluble substances are presented in Figure 2.

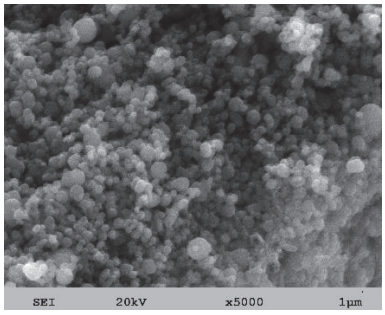

Fig. 2. Micrograph of quinoline insoluble substances isolated.

Coal tar is a complex multicomponent system including aromatic hydrocarbons (naphthalene, anthracene, phenanthrene), phenols, heterocyclic compounds and resinous components. The bulk of the compounds are characterized by a high degree of π-conjugation but relatively low polarity. Dielectric constant (ε) values depend on the specific composition, but for typical coal tar samples are in the range of 2.5-3.0, which is higher than that of saturated hydrocarbons but lower than that of polar aromatic compounds containing heteroatoms.

In electrodehydration processes, the efficiency of water droplet coalescence depends significantly on the dielectric permittivity contrast between the dispersed (water, ε ≈ 78 at 25 °C) and dispersed (oil or resin) phases. The higher this difference, the higher the induced dipole force in water droplets under the action of the electric field and, consequently, the higher the probability of their fusion. Thus, the coalescence conditions are more favorable for oil, which has minimal ε, than for the more polar coal tar.

Additionally, with increasing molecular weight and degree of condensation of aromatic structures, the dielectric constant of the resin tends to increase, especially in the presence of heteroatoms (O, N, S) involved in dipole-dipole interactions (Table 3).

TABLE III. VALUES OF DIELECTRIC CONSTANTS FOR INDIVIDUAL COMPONENTS OF COAL TAR AND SUBSTANCES INSOLUBLE IN QUINOLINE

Component	Dielectric constant
Coal tar	2.0÷3.0
Benzene	2.3
Toluene	2.4
Naphthalene	2.54
Phenanthrene	2.8
Anthracene	3.08
Quinoline	9
Phenol	9.9
Pyridine	12.5
Coal dust	1,2-1,8
Coke	1,1-2,2
Carbon black	2.5–3.0
Pyrolytic Carbon	4,0-6,0
Pyrite	7
Coal ash	4.6

Tars with higher density and degree of heat treatment (pyrolization) are characterized by higher aromaticity, which is accompanied by an increase in dielectric permittivity (ε) to values of the order of 3.0 and higher. This leads to a decrease in the efficiency of electrostatic dehydration, since the increased ε worsens the conditions of polarization and coalescence of water droplets in the electric field.

The increase in the content of high molecular weight heteroatom-containing aromatic compounds, as well as thermal modification of the tar contribute to a further increase in dielectric constant. Collectively, these changes impede electrodehydration, reducing the efficiency of phase separation processes.

The presence of fractions insoluble in quinoline (QI) also has a significant influence on the electrical characteristics of the tar. These particles have a high degree of aromaticity, low polarity and limited molecular mobility, despite the possible presence of heteroatoms. Due to their low polarizability, the QI fractions have a relatively low dielectric constant and therefore make a limited contribution to the overall ε value of the tar. Moreover, large or aggregated QI particles are able to screen the electric field, locally weakening it.

Some QI particles contain graphite-like carbon fragments or metal inclusions possessing electrical conductivity. In case of aggregation of such particles with formation of percolation pathways, it is possible to form continuous conductive channels. These structures can cross electric field lines or even create a short circuit between electrodes, forming a path with reduced resistance. As a result, the electric field strength in the working volume is reduced, the water is not polarized and does not move, which leads to a sharp deterioration of the dehydration efficiency. Additionally, the risk of localized electrical discharges and arcs that can cause equipment damage increases.

When the values of ε′ > 4 are exceeded in combination with increased electrical conductivity, the electric field starts to be lost in the form of thermal losses, which is critical for polarization processes of water droplets. The specific conductivity of such systems [9] varies widely and depends on the degree of aggregation and the conductive structure of QI. Near QI aggregations, microdischarge generation is possible, especially at high voltage.

Thus, the dielectric constant of coal tar containing QI fractions is significantly higher than that of purified tar (usually 2.5-3.5), which should be taken into account when designing electrostatic dewatering systems.

The results of calculation of the electric dehydrator performance depending on the density of tar oils and coal tar itself at removal of water droplets with a diameter of 220 microns are presented in Figure 3.

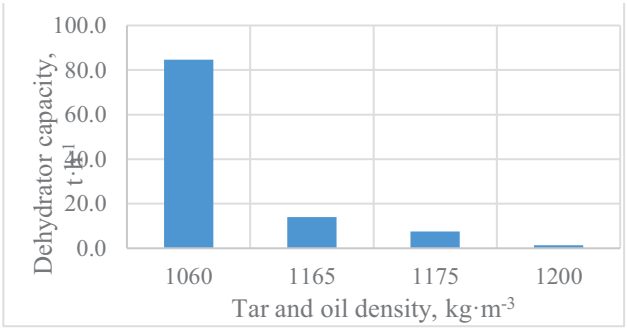

Fig. 3. Performance of dehydrator at application of emulsions with different density of constant phase (1060- density of resin fraction boiling out in the range of 230-300°C); 1165-1200- density of resin of different degree of pyrolization.

Consequently, the degree of pyrolyzation of coal tar significantly affects the performance of the electrodehydrator, as the increasing density and viscosity of the tar itself impede the rapid ascent of enlarged droplets formed by the coalescence of smaller droplets. Figure 4 shows the results of calculation of dehydrator productivity depending on the degree of pyrolisation of tar and the size of dispersed water droplets.

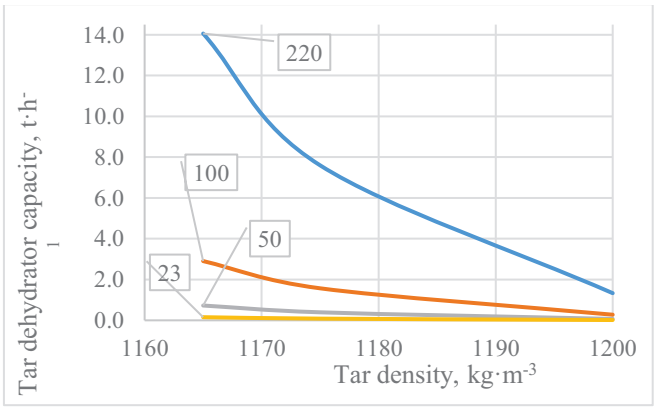

Fig. 4. Dependence of dehydrator productivity on the density of dewatered resin at different diameters of pop-up water droplets.

It follows from the Figure 4 that in order to increase the performance of the electric dehydrator for dewatering of heavy resins it is necessary that pop-up water droplets coalesced to form a united droplet with a diameter of at least 200 microns.

Experimental industrial trials of electric dehydrators for coal tar (density 1190 kg/m³) demonstrated that applying a voltage of 9.5–11 kV across 1×4 m² electrodes spaced 80–100 mm apart—achieving an electric field strength of 110–137 kV/m at 70–80°C—effectively reduces water content to below 3%. These results confirm the viability of electrostatic dewatering as a scalable, energy-efficient solution for meeting stringent industrial moisture specifications, surpassing traditional methods in both performance and operational efficiency.

IV. Conclusions

The dielectric properties and compositional complexity of coal tar—particularly its aromaticity, heteroatom content, and quinoline-insoluble (QI) fractions—critically influence the efficacy of electrostatic dewatering. Coal tar's dielectric constant (2.5–3.5), though higher than crude oil's, creates suboptimal polarization contrast with water (ε ≈ 78), reducing droplet coalescence efficiency compared to less polar oils. Furthermore, QI fractions with low polarity and conductive aggregates can shield or disrupt electric fields, risking short circuits and localized discharges, while elevated resin density and viscosity from pyrolysis hinder droplet separation. Calculations demonstrate that dehydrator performance declines sharply with increasing tar density (e.g., 1165–1200 kg/m³), necessitating coalesced water droplets ≥200 μm to maintain efficiency. Successful implementation of electrostatic dewatering thus requires tailored system designs to account for coal tar's variable dielectric behavior, QI content, and rheological properties, alongside optimized operational parameters like temperature, field strength, and droplet dynamics.

***Abstract* — the rapid proliferation of Internet of Things (IoT) devices has led to a significant increase in data generation, necessitating efficient edge computing solutions to minimize latency and enhance real-time processing. This paper presents a novel approach to task clustering and scheduling in IoT edge computing environments, utilizing a Differential Evolution (DE) algorithm. The proposed mechanism optimizes the allocation of computational tasks to available edge resources, reducing execution times and improving overall system efficiency. Key performance metrics demonstrate the effectiveness of the DE-based method in handling the dynamic and heterogeneous nature of IoT tasks, offering a scalable and robust solution for real-time IoT applications.**

Keywords* — *Internet of Things (IoT), Edge Computing, Resource Allocation, Task Optimization, Task Clustering, Task Scheduling, Real-time Processing, Differential Evolution

I. Introduction

The rapid expansion of the Internet of Things (IoT) has led to an unprecedented increase in the number of interconnected devices and sensors. These devices generate massive amounts of data, which traditionally have been processed in centralized cloud servers [1–3]. However, this approach introduces significant latency issues due to the physical distance between data sources and data processing centers. As real-time data processing becomes increasingly critical for applications such as autonomous vehicles, smart cities, and healthcare monitoring, the limitations of cloud computing have necessitated the development of more efficient data management solutions [4, 5]. IoT edge computing has emerged as a viable alternative, offering a decentralized approach where data is processed closer to its point of origin, thereby reducing latency and improving response times [6, 7].

The primary goal of this research is to enhance the efficiency of IoT edge computing systems by developing an innovative mechanism for task clustering and scheduling. By leveraging differential evolution optimization, the proposed mechanism aims to optimize the allocation of computational tasks to available resources at the edge. This research seeks to address the inherent challenges associated with IoT edge task management, such as the diverse nature of tasks, the limited computational capabilities of edge devices, and the dynamic and real-time requirements of IoT applications. To achieve this goal, the research focuses on several key tasks. First, a clustering mechanism will be developed to group IoT tasks based on their characteristics, such as task length, file size, number of required CPUs, and priority. This clustering process aims to ensure that tasks with similar requirements are processed together, enhancing resource utilization and minimizing execution time. Next, an efficient scheduling algorithm will be created to allocate the clustered tasks to appropriate edge computing resources. The scheduling mechanism will consider the current workload of resources to achieve a balanced distribution, thereby optimizing overall system performance.

Additionally, the differential evolution (DE) algorithm will be implemented and adapted for the specific context of IoT edge computing. The DE algorithm will be used to iteratively improve the clustering and scheduling process, ensuring that the solution converges to an optimal or near-optimal state. Key performance metrics, including execution time, system efficiency, and stability, will be measured to validate the effectiveness of the proposed mechanism. The goal is to demonstrate significant improvements in task execution times and overall system responsiveness compared to existing methods.

By achieving these tasks, this research aims to provide a scalable and efficient solution for task clustering and scheduling in IoT edge computing environments, ultimately enhancing the performance and reliability of real-time IoT applications.

II. Related Works

This literature review examines the optimization of task clustering and scheduling in IoT edge computing, a field that has garnered significant attention due to the increasing demand for efficient and low-latency data processing. Various strategies have been proposed to address the challenges inherent in managing diverse IoT tasks and resources. Several key studies have explored different heuristic and metaheuristic approaches to task clustering and scheduling.

One prominent method is the Particle Swarm Optimization (PSO) algorithm. Research conducted by Alhaizaey et al. (2022) demonstrated the effectiveness of PSO in distributing edge device tasks, optimizing makespan time, and reducing task allocation overhead. However, PSO's limitations in dynamic and heterogeneous IoT environments necessitate further refinement for broader applicability [8].

Another notable approach is the Firefly Algorithm (FA), which has been utilized by Yousif et al. (2021) to optimize cost and energy consumption in IoT edge computing

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

systems. While FA shows promise in specific scenarios, its performance in handling the dynamic nature of IoT tasks and resources requires improvement to achieve consistent efficiency across various workloads [9].

The integration of evolutionary algorithms in task clustering and scheduling has also been explored. The study by Azimi et al. (2020) introduced a multi-cluster edge layer framework, leveraging evolutionary mechanisms to minimize latency and delays in IoT edge tasks. This approach extended the capabilities of computational clouds to the IoT edge, showcasing the potential of evolutionary algorithms in managing semi-autonomous edge clusters [10].

Recent research has also considered the application of differential evolution (DE) algorithms in optimization problems. The work by Wang et al. (2022) applied a DE mechanism for energy-efficient task scheduling, addressing the discrete optimization requirements of IoT task scheduling. However, the study did not fully explore the multidimensional task characteristics specific to IoT edge computing environments [11].

Despite these advancements, existing mechanisms often fall short in addressing the unique constraints and real-time issues present in IoT edge task scheduling [12]. The proposed differential evolution (DE) mechanism by Kavitha et al. (2020) aims to fill this gap by providing a robust and scalable solution for task clustering and scheduling in IoT edge computing [13].

III. The Aim and Objectives of the Study

The primary goal of this research is to enhance the efficiency of IoT edge computing systems by developing an innovative mechanism for task clustering and scheduling using differential evolution optimization. This research seeks to develop a clustering mechanism to group IoT tasks based on characteristics such as task length, file size, number of required CPUs, and priority, ensuring tasks with similar requirements are processed together. Additionally, it aims to create an efficient scheduling algorithm to allocate the clustered tasks to appropriate edge computing resources, considering current workload to achieve balanced distribution and optimize system performance. The research will implement and adapt the differential evolution (DE) algorithm for the context of IoT edge computing to iteratively improve clustering and scheduling processes, aiming for optimal or near-optimal solutions. Key performance metrics, including execution time, system efficiency, and stability, will be measured to validate the effectiveness of the proposed mechanism compared to existing methods like FA and PSO. By achieving these tasks, this research seeks to provide a scalable and efficient solution for task clustering and scheduling in IoT edge computing environments, ultimately enhancing the performance and reliability of real-time IoT applications.

IV. Proposed Method

To address the challenges of task clustering and scheduling in IoT edge computing, this research proposes a novel mechanism leveraging differential evolution (DE) optimization. The proposed method is designed to optimize the allocation of computational tasks to available edge resources, thereby reducing execution times and improving overall system efficiency. This section outlines the various components of the proposed method, including the task clustering mechanism, the scheduling algorithm, the differential evolution optimization, and the mathematical representation.

A. Task Clustering Mechanism

The first step in the proposed method involves clustering IoT tasks based on their characteristics. The clustering mechanism groups tasks by considering factors such as task length, file size, number of required CPUs, and priority. This ensures that tasks with similar requirements are processed together, facilitating more efficient resource utilization. The similarity function $S(T_m, T_n)$ is used to measure the degree of similarity between tasks T_m and T_n. The function takes into account various task properties, and tasks with high similarity values are grouped into the same cluster.

The clustering process begins with the collection of task characteristics. Each IoT task is characterized by a set of attributes that describe its resource requirements and execution parameters. These attributes include task length, which represents the duration required to complete the task; file size, indicating the amount of data associated with the task; the number of CPUs required, which reflects the computational intensity; and task priority, which denotes the importance or urgency of the task. By analyzing these attributes, the similarity function can determine the degree of similarity between different tasks. The similarity function $S(T_m, T_n)$ is defined mathematically to quantify the similarity between two tasks. It calculates the similarity score based on the differences in their attributes. For instance, the similarity in task length is computed as:

$$S_{task_length}(T_m, T_n) = \\ = 1 \Big/ \left(1 + \left(\text{task_length}(T_m) - \text{task_length}(T_m)\right)\right), \quad (1)$$

where T_m and T_n are tasks for which the similarity function values are computed; $\text{task_length}(\bullet)$ is a function that determines the length of a specific task.

Similar equations are used to calculate the similarity scores for other attributes. The overall similarity score $S(T_m, T_n)$ is then obtained by averaging the individual similarity scores. Tasks with high overall similarity scores are grouped into the same cluster. Once the similarity scores are computed, the tasks are grouped into clusters using a clustering algorithm [14, 15]. This algorithm iteratively assigns tasks to clusters based on their similarity scores, ensuring that each cluster contains tasks with similar characteristics. The clustering process aims to minimize the intra-cluster variability while maximizing the inter-cluster variability. This approach not only enhances resource utilization but also simplifies the scheduling process by reducing the variability within each cluster.

B. Task Scheduling Algorithm

Once the tasks are clustered, the next step is to allocate these clusters to suitable edge computing resources. The proposed scheduling algorithm aims to balance the workload across resources, minimizing execution times and optimizing system performance. The scheduling process involves mapping each task cluster to an edge resource based on the current workload and resource capabilities. The algorithm ensures that high-workload tasks are allocated to

less busy resources and vice versa, thus achieving a balanced distribution.

The scheduling algorithm operates in several phases. Initially, it assesses the current workload of each edge resource, considering factors such as CPU utilization, memory usage, and network bandwidth. This assessment helps in understanding the current state of the resources and their availability for additional tasks. The algorithm then assigns task clusters to resources in a manner that balances the load, avoiding overburdening any single resource.

The allocation of task clusters to resources is performed using a heuristic approach that takes into account the current workload and the resource capabilities [16]. The heuristic aims to minimize the overall execution time by distributing the workload evenly across all available resources. The algorithm starts by sorting the task clusters based on their total workload. It then iteratively assigns the task clusters to the least loaded resource, updating the resource load after each assignment. This dynamic allocation process is continuously refined to adapt to changing workloads and resource conditions, ensuring optimal performance at all times.

The scheduling algorithm also incorporates a feedback mechanism to monitor the performance of the allocated tasks. This feedback is used to adjust the allocation strategy in real-time, addressing any imbalances that may arise during execution. By continuously monitoring and adjusting the allocation, the algorithm ensures that the resources are utilized efficiently and that the execution times are minimized.

C. Differential Evolution (DE) Optimization

The core of the proposed method is the differential evolution optimization algorithm. DE is an evolutionary algorithm that iteratively improves candidate solutions through mutation, crossover, and selection processes. In the context of IoT edge computing, the DE algorithm is adapted to handle the discrete nature of task clustering and scheduling. The DE optimization process begins with the initialization of a random population of candidate solutions. Each solution represents a potential allocation of tasks to clusters and resources. The fitness of each solution is evaluated based on the total execution time of the tasks. The algorithm then generates new candidate solutions by combining existing ones using mutation and crossover operations. The best-performing solutions are selected for the next generation, and this process is repeated until the optimization converges to an optimal or near-optimal solution.

The mutation operation in DE involves creating a mutant vector by adding the weighted difference between two population vectors to a third vector. This operation introduces variation into the population, allowing the algorithm to explore a wide range of potential solutions. The crossover operation combines elements from the mutant vector and the target vector to create a trial vector. This operation ensures that the new candidate solutions inherit characteristics from multiple parents, increasing the diversity of the population.

The selection operation evaluates the fitness of the trial vector and compares it with the fitness of the target vector. If the trial vector has a better fitness value, it replaces the target vector in the population. This selection process ensures that the population gradually evolves towards better solutions over successive generations.

In the context of IoT edge computing, the DE algorithm is adapted to handle the discrete nature of task clustering and scheduling. The candidate solutions are represented as discrete vectors, where each element indicates the assignment of a task to a cluster and a resource. The fitness function evaluates the total execution time of the tasks, considering the workload distribution and resource capabilities. By iteratively refining the candidate solutions, the DE algorithm identifies high-quality solutions that minimize execution times and maximize resource efficiency.

D. Mathematical Representation

The task clustering and scheduling problem is represented mathematically to facilitate the application of the DE algorithm. Let $T = \left\{T_i, j = \overline{1,I}\right\}$ be the set of IoT tasks, $C = \left\{C_j, j = \overline{1,J}\right\}$ be the set of task clusters, and $R = \left\{R_k, k = \overline{1,K}\right\}$ be the set of edge resources. The variable x_{ijk} represents the assignment of task T_i to cluster C_j and resource R_k, where $x_{ijk} = 1$ if the task is assigned and 0 otherwise. The objective function to minimize the total execution time Z is given by:

$$Z = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} x_{ijk} \cdot e_{ijk} \underset{t}{\rightarrow} \min, \tag{1}$$

where e_{ijk} is the execution time of task T_i in cluster C_j on resource R_k, t – criterion for minimization based on the total execution time of tasks. The constraints ensure that each task is assigned to exactly one cluster and one resource, and that the total number of tasks assigned to a resource does not exceed its capacity.

The mathematical formulation provides a clear and concise representation of the optimization problem, enabling the DE algorithm to operate effectively. By defining the objective function and constraints, it ensures that the algorithm focuses on minimizing execution times while adhering to resource limitations. This structured approach is essential for achieving optimal task allocation in complex IoT edge computing environments.

The constraints are defined as follows:

- Each task is assigned to exactly one cluster and one resource:

$$\sum_{j=1}^{J}\sum_{k=1}^{K} x_{ijk} \le 1 \quad \forall i \in \overline{1,I}, \tag{2}$$

- The total number of tasks assigned to a resource should not exceed its capacity:

$$\sum_{i=1}^{I}\sum_{j=1}^{J} x_{ijk} \cdot r_{ijk} \le n_k \quad \forall k \in \overline{1,K}, \tag{3}$$

where r_{ijk} – amount of resource R_k, required for executing task T_i, assigned to cluster C_j, n_k – maximum available amount of resource R_k.

By incorporating these constraints into the optimization problem, the DE algorithm can effectively allocate tasks to clusters and resources while ensuring that the resource capacities are not exceeded [17]. The mathematical representation provides a robust framework for the optimization process, guiding the algorithm towards feasible and optimal solutions.

V. Results and Discussion

To assess the effectiveness of the proposed method, simulations were carried out in a controlled Industrial IoT (IIoT) environment. The performance was benchmarked against two established metaheuristic algorithms: Particle Swarm Optimization (PSO) and the Firefly Algorithm (FA), based on a consistent set of evaluation metrics. The results highlight the advantages of the proposed approach in terms of execution time, resource utilization, network overhead, and load balancing.

A. Environment

Simulations were conducted using a custom model of an IIoT system comprising three edge computing nodes with uniform capabilities. Each node was equipped with 8 logical CPU units and connected via a local 1 Gbps network with a round-trip latency of approximately 50 milliseconds. A total of 100 tasks were generated per experiment. Each task was defined by a random execution length, data size, required CPU resources, and priority level. Tasks were initially assigned to original nodes and could be executed locally or offloaded, with network latency added in the latter case. To ensure statistical robustness, each scheduling method was evaluated over 250 independent iterations. Final results were obtained by averaging the values, providing a representative assessment of each method's effectiveness.

B. Evaluation Metrics

The effectiveness of the scheduling methods was evaluated using four key performance metrics relevant to the requirements of real-time edge computing in IIoT environments:

- Total execution time (makespan) — measures the time required to complete the full batch of tasks from start to finish. Minimizing execution time is critical in IIoT systems where latency directly affects responsiveness, process control, and system throughput;
- Average CPU utilization — represents the ratio of active processing time to the total available CPU time across all edge nodes. Higher utilization indicates more efficient use of computing resources, reducing idle time and increasing overall system productivity;
- Average network latency — accounts for the communication delay introduced when tasks are offloaded from their origin node to another processing node. This metric reflects the trade-off between computational balancing and the cost of data transfer across the network;
- Load balancing efficiency — quantifies how evenly the workload is distributed across all available edge nodes. Better balance reduces the risk of overloading individual nodes and helps maintain consistent performance under varying workloads.

These metrics were selected to reflect the core challenges of IIoT edge computing: ensuring low-latency task completion, maximizing the utility of limited edge resources, and minimizing inter-node communication overhead. A high-performing scheduling algorithm must strike a balance across all four criteria to be viable in dynamic, real-world deployments.

C. Results

The experimental comparison highlights clear advantages of the proposed method over PSO and FA. By effectively distributing the computational load and minimizing unnecessary task migrations, the proposed method achieves the shortest execution time, the highest CPU utilization, and the most balanced workload allocation. These characteristics are especially important for IIoT systems, where responsiveness and efficiency under constrained resources are critical. The comparison of execution times, presented in Fig. 1, reveals clear differences in scheduling efficiency among the evaluated methods. The proposed approach achieves the shortest overall makespan, demonstrating its ability to complete the entire workload more rapidly than PSO and FA. This outcome highlights the effectiveness of the method's task allocation strategy, which reduces idle time and maximizes concurrency. In contrast, FA results in the longest execution time due to its limited offloading behavior, which prevents efficient workload distribution across edge nodes.

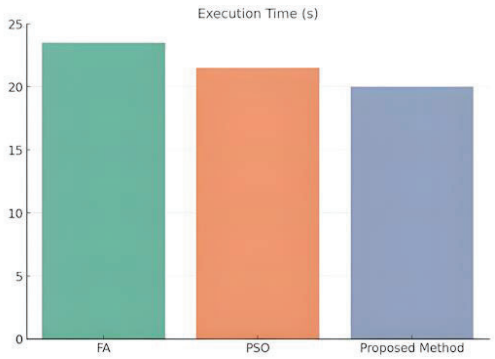

Fig. 1. Comparison of the scheduling methods in terms of execution time

Fig. 2 illustrates the average CPU utilization observed for each method during task execution. The proposed method maintains the highest utilization across the edge infrastructure, indicating more efficient exploitation of available processing resources. This suggests that the method not only schedules tasks promptly but also minimizes underutilization of computational capacity. PSO performs reasonably well but still exhibits periods of partial idleness. FA, which restricts task migration, results in the lowest CPU utilization due to uneven task accumulation and imbalanced processing. The average network latency introduced by task offloading is analyzed in Fig. 3. As expected, FA produces the lowest communication overhead by prioritizing local task execution and avoiding cross-node transfers. However, this conservative behavior comes at the cost of lower system-level efficiency. PSO, on the other hand, incurs the highest latency due to its aggressive offloading strategy. The proposed method demonstrates a balanced behavior, maintaining moderate latency while achieving superior performance in other critical metrics, which reflects an effective trade-off between load distribution and communication cost.

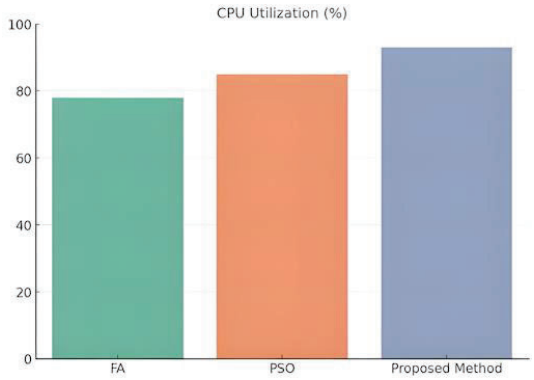

Fig. 2. Comparison of the scheduling methods in terms of CPU utilization

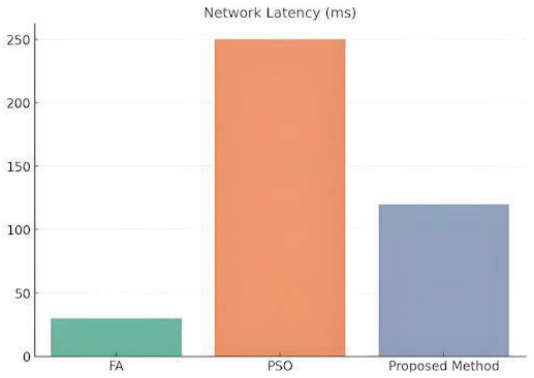

Fig. 3. Comparison of the scheduling methods in terms of network latency

Fig. 4 presents the results related to load balancing efficiency across the edge nodes. The proposed method attains the most uniform distribution of tasks, minimizing disparities in processing workload and ensuring that all nodes contribute evenly to task execution. This balance reduces the likelihood of node saturation or underuse, enhancing the overall responsiveness and scalability of the system. PSO achieves partial load balancing but remains suboptimal, while FA demonstrates the weakest performance in this metric due to its preference for local-only execution.

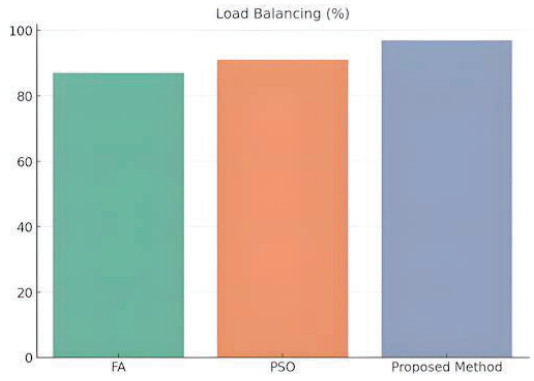

Fig. 4. Comparison of the scheduling methods in terms of load balancing

The numerical results presented in Table 1 provide a consolidated view of the performance achieved by each scheduling method across the defined evaluation metrics. The proposed method consistently outperforms both PSO and FA, achieving the shortest execution time, the highest CPU utilization, and the most balanced workload distribution, while maintaining moderate network latency.

TABLE I. Comparison of the scheduling methods across the metrics

Iteration No.	FA	PSO	Proposed Method
Execution Time (s)			
5	23.15	21.57	20.06
10	23.49	21.55	19.62
50	23.33	21.67	20.01
100	23.31	21.61	20.02
150	23.77	21.56	19.62
200	23.71	21.68	19.63
250	23.98	21.27	20.3
Avg.	**23.5**	**21.5**	**20**
CPU Utilization (%)			
5	76.65	84.23	94.22
10	78.12	84.95	97.93
50	78.96	84.04	93.67
100	76.8	82.33	93.64
150	77.68	95.23	94.34
200	75.01	83.14	91.7

250	87.33	89.76	96.84
Avg.	**87**	**91**	**97**

These results demonstrate the method's ability to optimize task allocation effectively without incurring excessive communication overhead. While FA achieves minimal network delay, it performs poorly in all other aspects, particularly execution time and resource utilization. PSO delivers more balanced performance but is limited by increased offloading cost and suboptimal workload distribution. Overall, the table confirms that the proposed approach provides the most favorable trade-off across all key performance indicators in the IIoT scheduling context.

D. Discussion

The results confirm the ability of the proposed method to effectively cluster and schedule tasks in heterogeneous IIoT edge environments. The method maintains a strong balance between processing efficiency and communication cost. It improves makespan and load distribution while limiting unnecessary offloading. These properties make it suitable for deployment in resource-constrained real-time edge systems where responsiveness and scalability are critical.

VI. Conclusion

The research presented in this study has demonstrated the efficacy of a differential evolution (DE) mechanism for optimizing task clustering and scheduling in IoT edge computing environments. The proposed DE-based method

significantly improves execution times and resource utilization compared to established optimization techniques such as the Firefly Algorithm (FA) and Particle Swarm Optimization (PSO). This conclusion is based on the superior performance of the DE mechanism in handling the dynamic and heterogeneous nature of IoT tasks and resources.

A key contribution of this research is the development of a task clustering mechanism that groups tasks based on their characteristics, such as task length, file size, number of required CPUs, and priority. This clustering approach ensures that tasks with similar requirements are processed together, which enhances resource efficiency and reduces execution times. The scheduling algorithm, which dynamically allocates these clustered tasks to the most suitable edge resources, further optimizes system performance by balancing the workload in real-time.

The DE optimization process, characterized by its iterative improvement through mutation, crossover, and selection operations, enables the proposed method to effectively explore and exploit the solution space. This robust optimization framework allows the DE mechanism to consistently identify optimal or near-optimal solutions, even in complex and rapidly changing IoT environments. The integration of a feedback mechanism that continuously monitors and adjusts task allocations ensures that the system remains balanced and efficient throughout its operation.

The mathematical representation of the task clustering and scheduling problem provided a clear and structured framework for the DE algorithm. This formalization ensured that the optimization process adhered to the constraints of resource capacities and task requirements, leading to feasible and effective solutions. This structured approach addresses the limitations of previous heuristic and ad-hoc methods, providing a more reliable and consistent optimization strategy.

The experimental evaluation further supports these findings. Compared to PSO and FA, the proposed method achieved superior results across all key performance metrics, including execution time, CPU utilization, network latency, and load balancing efficiency. This consistent advantage under controlled IIoT conditions confirms the method's practical value and robustness, highlighting its potential for deployment in real-time edge computing systems with dynamic workloads.

The prospects of this research are promising. The DE-based mechanism's adaptability and efficiency make it well-suited for real-time IoT applications, where the ability to process data quickly and efficiently is critical. Future research could explore the integration of other optimization techniques with DE to further enhance its performance. Additionally, the application of this method to other areas of edge computing and its scalability to larger IoT networks are potential avenues for further investigation.

In conclusion, the proposed method for task clustering and scheduling in IoT edge computing represents a significant advancement in the field. It offers a scalable, efficient, and robust solution that enhances the performance and reliability of IoT applications. This research not only validates the potential of differential evolution in optimizing IoT edge computing systems but also sets a new standard for future studies in this domain.

***Abstract*—The paper investigates the problem of detecting and localizing biological objects in microscopic images using deep learning methods. The main attention is paid to the automated creation of annotated datasets for training deep learning models, which is a relevant task in biomedical applications, where manual labeling is laborious and expensive. A method for automatically generating blood cell labeling using classical computer vision methods and the k-means clustering algorithm is proposed. The resulting dataset was adapted to the format of YOLO models (versions YOLOv8 and YOLOv11), which were used for cell detection and classification. A comparative analysis of the results of model training was performed using the metrics of accuracy, completeness, average accuracy (mAP), and speed. The YOLOv8 model showed higher accuracy and stability, while YOLOv11 was characterized by higher processing speed. The results demonstrate the effectiveness of using automatically annotated data for computer vision tasks in biomedicine and confirm the feasibility of further improving approaches to automatic image labeling.**

Keywords—computer vision, optimization, object detection, YOLO, deep learning, biomedical image analysis, automatic annotation, k-means clustering, image processing, microscopic images, blood cell classification

I. INTRODUCTION

Image recognition is a key task in modern biomedicine, diagnostics, scientific research, and laboratory automation. It involves the automatic recognition and localization of cells, tissues, organelles, or other structures in microscopic, X-ray, tomographic, or macroscopic images.

The modern view of the problem of object detection, localization and segmentation is to consider such tasks as deep learning problems due to the ability of such an approach to effectively process complex, high-dimensional and visually variable data like images [1]. Classical computer vision algorithms based on rules, filters and manually developed features, although successful in some application cases, are significantly limited in the real biological environment, where objects can be distorted, partially overlapped, differ in size, shape or color.

Deep learning, specifically convolutional neural networks, allows for automatic learning of features from data, without the need for manual intervention. This means that the model can detect complex patterns and contexts that are difficult or even impossible to describe manually. In the case of biological objects – cells, bacteria, and tissue structures – this is especially valuable, as their appearance varies greatly depending on the staining method, equipment, patient, or stage of disease.

In addition, deep learning scales well – the more data we have, the better the model can work. This allows us to create highly accurate systems for detecting even very rare or inconspicuous biological structures. Modern methods provide not only classification, but also localization of objects in images, which makes them ideal for detection tasks. In addition, deep learning is easily adaptable to new tasks. Transfer learning enables the adaptation of models pre-trained on large-scale general image datasets to domain-specific biomedical tasks, achieving high performance even with limited training data.

But by their nature, deep learning methods used in computer vision are supervised machine learning methods, and therefore require annotated datasets. On the other hand, the task of object detection and localization can be considered a data science task, because the task of detecting objects in images is not just a technical implementation of a certain neural network model. It covers the entire data processing cycle inherent in data science: data collection, data preparation, data analysis and visualization, modeling, evaluation, and deployment. Moreover, according to [2], the first 3 stages take up to 85% of the time of a data scientist. So, one of the ways to optimize the time spent on the object detection process is to automatically create annotated datasets.

II. LITERATURE REVIEW

In a number of studies [3, 4, 5], approaches, algorithmic solutions, and experimental research results related to the automated creation of annotated data sets for their further use in machine learning tasks, in particular for the detection, localization, and segmentation of objects in images, were analyzed. In [4], a basic algorithm was proposed for the

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

detection and classification of blood cells in microscopic images. The main tool of this approach was image processing methods, which allowed performing cell segmentation, i.e., isolating objects in the image. After the segmentation stage, the cells were classified by the area of the detected objects, which allowed them to be assigned to one of three classes: platelets, erythrocytes (red blood cells – RBC), or leukocytes (white blood cells – WBC).

In [3], this approach was adapted to generate an annotated dataset in CSV format, which stored the relevant metadata for each image: file name, bounding box coordinates of each object found, and its type. The classification was also based on empirically determined cell area sizes, which allowed for automatic label generation without the involvement of experts for the labeling process.

A later study [5] built on the approach proposed in [3], improving and extending it to support the creation of annotated datasets not just for blood cells, but for any objects found in microscopic images. In order to automatically classify segmented objects into classes, the k-means clustering algorithm was used, which made it possible to avoid manual area analysis and increase the versatility of the technique.

This study examines the practical use of the resulting automatically annotated dataset as a base for training deep learning models designed to accurately detect, localize, and classify cells in microscopic images.

III. Problem Statement

The task of detecting multiple objects in an image is to find all objects of given classes in the input image and determine their spatial boundaries (bounding boxes) along with the corresponding class labels.

Mathematically, the problem of detecting objects in images can be formalized as follows:

A set of images is given

$$X = \left\{ x_i \in \Re^{H \times W \times 3} \,\middle|\, i = 1,2,...,N \right\}, \tag{1}$$

where each image x_i has height H, width W, and 3 color channels (RGB).

For each image x_i there are a set of annotated objects:

$$Y_i = \left\{ \left(b_{ij}, c_{ij} \right) \middle| i = 1,2,...,M_i \right\}, \tag{2}$$

where M_i – number of objects in the image x_i; $b_i = \left(x_{ij}, y_{ij}, w_{ij}, h_{ij} \right)$ are center coordinates (sometimes the coordinates of the upper left corner can be considered – depending on the type of data set representation), width and height of the object's bounding box j in the picture i; $c_{ij} \{1,2,...,C\}$ is a object class label belonging to one of C possible classes.

The goal is to construct a function

$$f : \Re^{H \times W \times 3} \to \left| \left(\hat{b}, \hat{c}, s \right) \right|, \tag{3}$$

which for each image returns a finite set of tuples $\left(\hat{b}, \hat{c}, s \right)$, where $\hat{b} \in \Re^4$ is the object predicted bounding box, $\hat{c} \in \{1,2,...,C\}$ is the object class, $s_i \in [0,1]$ is the degree of confidence of the model in this prediction.

The model is trained by minimizing the total loss function

$$L = L_{cls} + \lambda \cdot L_{loc}, \tag{4}$$

where L_{cls} is a classification loss function, L_{loc} is a coordinates regression loss function, $\lambda \in \Re_+$ is a weight coefficient that regulates the importance of localization.

IV. Overview of Tools and Models Used

To implement image processing and object segmentation methods, the OpenCV library was used, which provided functionality for filtering, binarization, and contour extraction. Metadata processing and storage were performed using the Pandas and NumPy libraries. The k-means algorithm from the Scikit-learn library was used for automatic clustering and pre-classification of objects [5].

Two modern architectures were tested to build object detection models: YOLO (You Only Look Once), implemented using the Ultralytics frameworks: YOLOv8 and YOLOv11 [6]. This architecture provided high image processing speed and became suitable for applications where performance is critical.

The generated annotations in CSV format were adapted to the requirements of each model, which made it possible to effectively use automatically generated data for training and validating deep learning models.

V. Training the YOLOv8/YOLOv11 Model

As a result of applying the methodology considered in [5], a data set was created in CSV format with the following columns:

– `file_name` is an image file name;

– `xmin`, `ymin`, `xmax`, `ymax` are coordinates of the upper left and lower right corners of the bounding box;

– `type` is a cell type.

For YOLO models, the dataset must be in a specific format [7].

The directory structure should correspond to the structure given in Fig. 1. That is, the dataset should be divided into an image part and an annotation part.

```
yolo_dataset/
├── images/
│   ├── train/
│   └── val/
├── labels/
│   ├── train/
│   └── val/
```

Fig. 1. Directory structure of YOLO dataset

The annotations for the YOLO model should in turn be provided in a text file with the same name as the image. Each text file should contain information in the format

`<class_id> <x_center> <y_center> <width> <height>,`

where `class_id` is an integer (0, 1, 2, …) corresponding to the class; `x_center`, `y_center` is the center of the object, normalized to [0, 1]; `width`, `height` are the width and height of the bounding box, also normalized to [0, 1].

To convert the data set obtained in [5], a sequence of actions is proposed. The process begins with defining input parameters, including the path to the CSV file with annotations, the directory with the corresponding images, and the directory for outputting the results, and a class map that maps object names to the numeric identifiers (`class_id`) required for the YOLO format.

After that, the CSV data is read into a structure conveniently presented as a DataFrame, which allows easy filtering and processing of information. At this stage, the names of object types are also transformed into numerical indices that will be used when generating labels. Next, a directory structure is created that corresponds to the format expected by the YOLO framework: separate folders for images and labels, which are divided into training and validation samples (train and val).

All unique image names mentioned in the CSV are collected and divided into train and val subsets. This ensures balance and reliability during model training and testing. Next, the image processing stage begins. For each image, its presence in the input directory is checked. If the file is missing, processing is skipped. If the file is found, its size is read, after which all objects corresponding to this image are selected from the CSV file.

An important step is to convert the object coordinates from absolute values to the normalized YOLO format – the center of the object and its dimensions in relative coordinates (from 0 to 1). For each object, a text string is created in the appropriate format, which will later be written to a text file with the same name as the corresponding image.

After generating the labels and formatting them in a YOLO-compatible format, the image is copied to the appropriate subfolder (train or val), and the generated .txt file with the labels is saved in a similar substructure. The final step in the entire process is to create a configuration file dataset.yaml, which contains the paths to the data subsets, the number of classes, and their names. This file serves as a key element for further running the training process.

After applying the algorithm, each image annotation file looks like this:

```
0 0.659722 0.873278 0.058333 0.055096
0 0.425000 0.853994 0.066667 0.066116

```

Fig. 2. Contents of the annotation file

Model training was performed in the Google Colab environment using the T4 GPU (NVIDIA Tesla T4) [8].

The result of detection and localization using bounding boxes is given in Fig. 3.

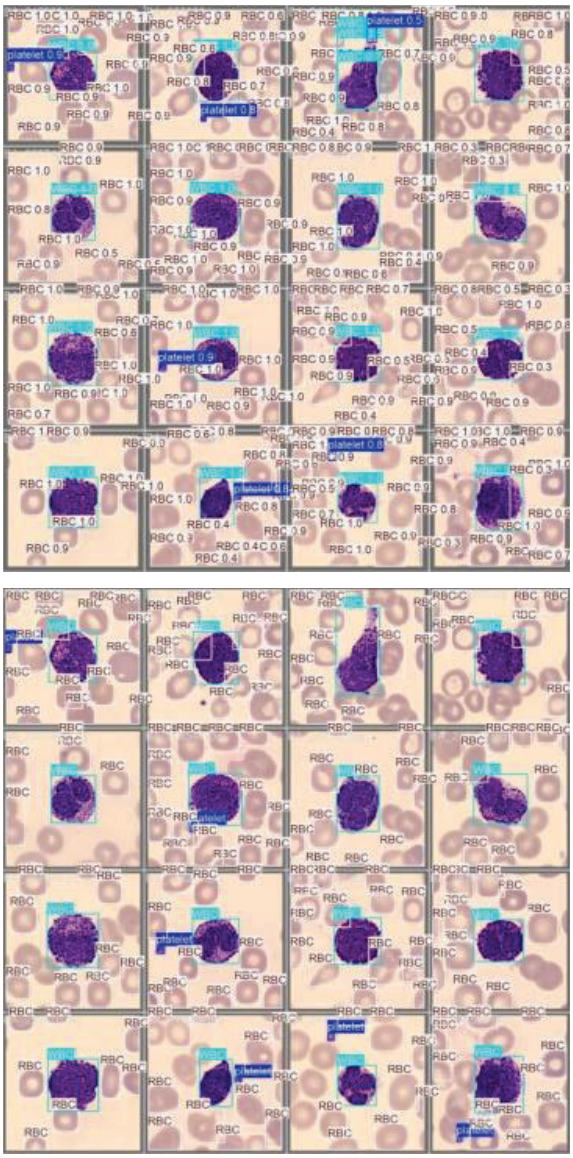

Fig. 3. Result of blood cell localization using YOLOv8 and YOLOv11 models

The results of training and validation of the YOLOv8 and YOLOv11 models are given in Table 1.

TABLE I. MODEL TRAINING QUALITY METRICS

Metrics	YOLOv8	YOLOv11
precision	0.909	0.834
recall	0.855	0.86
mAP50	0.879	0.867
mAP50-95	0.788	0.756
fitness	0.797	0.766
preprocess	0.197	0.0855
inference	2.005	1.193
loss	0.0004	0.0004
post-process	1.697	1.538

The Table 1 shows a comparative analysis of the two versions of the YOLO model in terms of accuracy, efficiency, and performance. First, we present the classic metrics for assessing the quality of computer vision models: precision, recall, mAP50(B), mAP50–95, and the aggregate fitness indicator, which is often used as a weighted combination of previous metrics for a generalized assessment.

YOLOv8 shows slightly higher precision (0.909) compared to YOLOv11 (0.834), but YOLOv11 has a slight advantage in recall (0.86 vs. 0.855). mAP metrics, which measure average accuracy at different IoU thresholds, also show better performance for YOLOv8 at a threshold of 0.5 (0.879 vs. 0.867), but a decrease in accuracy in the range of 0.5–0.95 is typical for both models. The fitness indicator is higher for YOLOv8 (0.797 vs. 0.766), indicating a better overall balance of this version.

The next part of the table concerns the performance of the models, i.e. the time required to perform each of the image processing stages: preprocessing, inference (prediction itself), calculation of the loss function and postprocessing of the results. YOLOv11 significantly outperforms YOLOv8 in terms of speed at all stages. In particular, the inference time of YOLOv11 is 1.193ms versus 2.005ms in YOLOv8, which is almost twice as fast. This may indicate an optimization of the architecture or a reduction in the amount of calculations. Despite the same loss value (0.0004), the overall performance of YOLOv11 indicates its potential advantage for real-time tasks.

Thus, the data from the table illustrates a typical trade-off between recognition accuracy and speed, where YOLOv8 shows better prediction quality, and YOLOv11 shows higher speed. The choice of model depends on the requirements of a particular application: if high accuracy is important, then you should choose YOLOv8; if speed is critical, then YOLOv11 will be a better candidate.

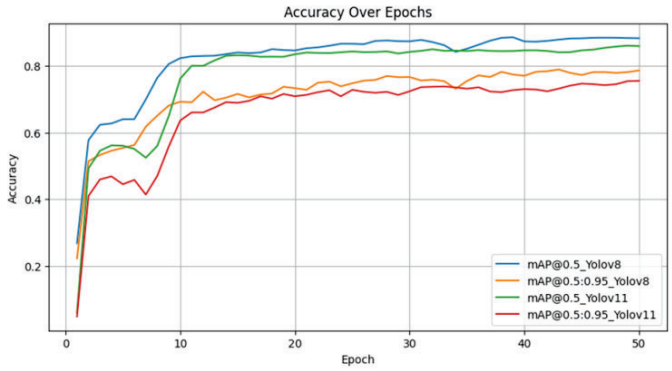

Fig. 4. Model learning dynamics

The graph presented in Fig. 4 shows the dynamics of changes in the accuracy of the YOLOv8 and YOLOv11 models during the training process for 50 epochs. The X-axis shows the number of epochs, while the Y-axis displays the accuracy values according to two metrics – mAP@0.5 and mAP@0.5:0.95. These metrics are standard for assessing the quality of object recognition models: the first is less demanding and takes into account positive predictions that have at least 50% intersection with the real object, the second is more strict and displays the average accuracy at different IoU thresholds from 0.5 to 0.95.

According to the graph, the YOLOv8 model demonstrates significantly higher accuracy compared to YOLOv11 on both metrics. Already at the first stages of training, a rapid increase in mAP values for YOLOv8 is visible – by about the 10th epoch it reaches high results and then only slightly fluctuates around a stable level. In particular, mAP@0.5 for YOLOv8 exceeds 0.85, while its accuracy according to the stricter criterion mAP@0.5:0.95 is kept within 0.75.

Against this background, YOLOv11 looks weaker: although its mAP@0.5 also increases and approaches the level of YOLOv8, the lag is still noticeable. The largest gap is observed in the accuracy of the mAP@0.5:0.95 metric, which in YOLOv11 remains at about 0.70, falling behind YOLOv8 by almost 5 percent.

These results indicate that YOLOv8 is better able to learn and generalize quickly, even at early stages. It can be assumed that the architecture of this model is more optimized, or that its hyperparameters are better matched to the data used for training. In any case, the graph analysis convincingly demonstrates the superiority of YOLOv8 over the experimental YOLOv11, especially in the context of high-accuracy scenarios, where the mAP@0.5:0.95 metric is critical.

VI. MODEL TESTING

The results presented in Table 1 are obtained based on the validation that was performed on an automatically generated dataset. This dataset contains undetected and incorrectly detected objects of all classes [5]. Therefore, to check the efficiency of object recognition, manual testing was performed on 150 images [9]. We will consider the problem of object detection in an image, so we can formalize the problem of testing the model as a multiclass and multiobject problem.

The task of classifying a set of objects in images can be viewed as a task of element-wise comparison of vectors of quantities by class, followed by the formation of partial estimates for each class. This approach allows us to evaluate the performance of models in the tasks of counting and classifying biological objects without resorting to more complex methods of position analysis or geometric characteristics.

We have a set of images I_n, where $i = 1, 2, ..., N$, and the number of possible classes is denoted as K. For each image, a vector of real values is given $Y^{(i)} = \left(y_1^{(i)}, y_2^{(i)}, ..., y_K^{(i)}\right)$, where $y_k^{(i)} \in N_0$ indicates the number of objects k-th class that are actually present in the image. Similarly, the model generates a vector of predicted values $\hat{Y}^{(i)} = \left(\hat{y}_1^{(i)}, \hat{y}_2^{(i)}, ..., \hat{y}_K^{(i)}\right)$, where each component represents the number of objects of the class k detected in the image by the model.

Since the task is to correctly identify only the classes and their quantities, we can form an independent estimate of the classification accuracy for each class using the sums over all images. In particular, for each class k. The number of correct predictions is determined, that is cases where both the model and the label agree on the number of objects of this class. In a simplified approximation, the model is considered to have correctly classified objects if the number of predicted

objects does not exceed the number of real objects, and we can interpret the minimum between these two values as the number of true positives.

Thus, for each class k the total value of true positive predictions is defined as the sum

$$TP_k = \sum_{i=1}^{N} \min\left(y_k^{(i)}, \hat{y}_k^{(i)}\right). \quad (5)$$

The number of false positives for a class is the total excess of predicted objects over the actual ones:

$$FP_k = \sum_{i=1}^{N} \max\left(\hat{y}_k^{(i)} - y_k^{(i)}, 0\right), \quad (6)$$

and false negatives – the lack of predictions compared to the actual number:

$$FN_k = \sum_{i=1}^{N} \max\left(y_k^{(i)} - \hat{y}_k^{(i)}, 0\right). \quad (7)$$

These values allow us to construct confusion matrices (Fig. 5 – 7), as well as to determine standard classification quality metrics: precision, recall, and F1-measure [3] for each class (Table 2).

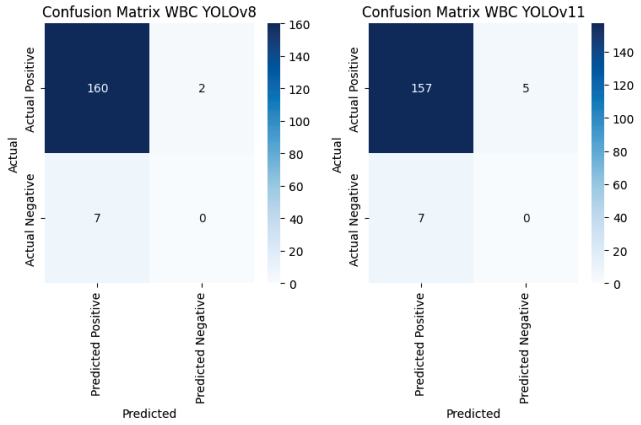

Fig. 5. Error matrices for leukocytes

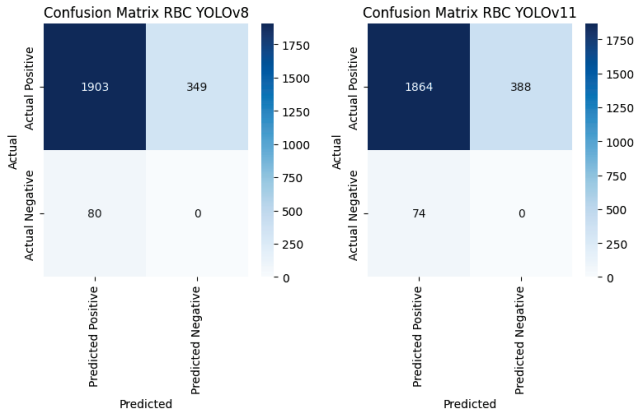

Fig. 6. Confusion matrix for red blood cells

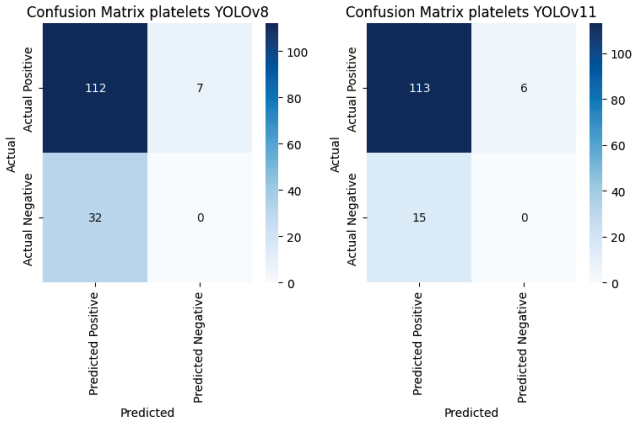

Fig. 7. Error matrices for platelets

TABLE II. MODEL QUALITY METRICS

Metrics	YOLOv8			YOLOv11		
	WBCs	RBCs	Platelets	WBCs	RBCs	Platelets
Accuracy	0.9467	0.8160	0.7417	0.9290	0.8014	0.8433
Precision	0.9581	0.9597	0.7778	0.9573	0.9618	0.8828
Recall	0.9877	0.8450	0.9412	0.9691	0.8277	0.9496
F1	0.9726	0.8987	0.8517	0.9632	0.8897	0.9150

A comparison of the YOLOv8 and YOLOv11 models (Fig. 8 – 9) for the blood cell recognition task demonstrates interesting dynamics of changes in the classification quality of the three main cell types: leukocytes (WBCs), erythrocytes (RBCs), and platelets (Platelets). Although the overall picture of the metrics for the models looks quite similar, a detailed analysis reveals key advantages and disadvantages of each of them.

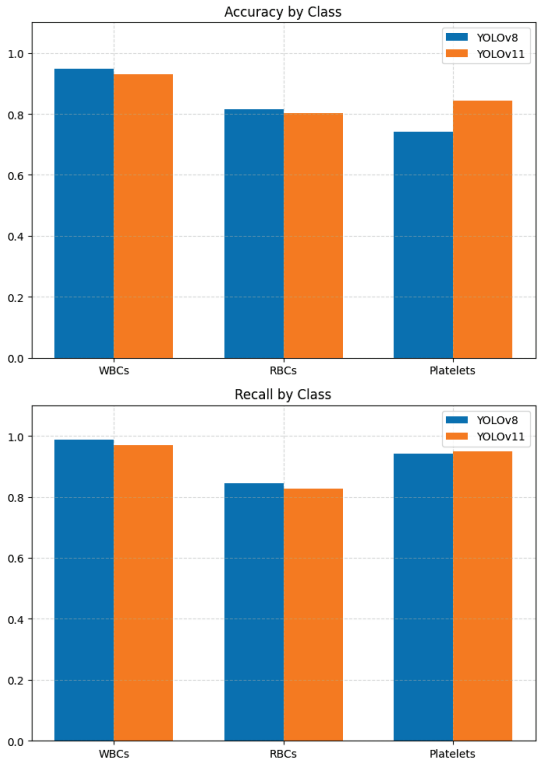

Fig. 8. Comparison of quality metrics

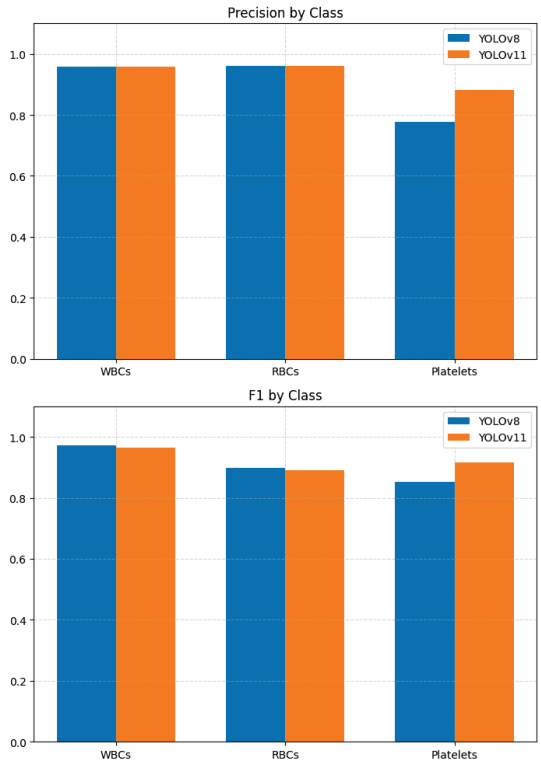

Fig. 9. Comparison of quality metrics

YOLOv8 demonstrates a high level of accuracy and completeness in the detection of leukocytes. Its recall reaches almost 99% and the F1 metric is over 97%, indicating a very small number of missed objects in this class. This makes YOLOv8 extremely reliable in detecting large and well-defined cells such as WBCs. For erythrocytes, the model also shows confident results, especially in terms of precision and the balance between precision and recall, as reflected in the F1 metric, which exceeds 89%.

In turn, YOLOv11 brings a significant improvement in the platelet category – the smallest cells, which are often difficult to detect due to their similarity to artifacts or image noise. All key metrics increase significantly compared to YOLOv8, making the newer model much more effective in this difficult sub-task. This suggests that YOLOv11 has a better ability to focus on small details or uses more optimized architectural components or loss functions that are better suited to detecting such objects.

Despite these improvements, YOLOv11 slightly loses accuracy and F1-metric in recognizing WBCs and RBCs compared to YOLOv8. These differences are not critical, but they highlight that optimizing a model for one class (platelets) can come at the expense of others.

Thus, the choice of model depends on the application goals. If the main task is the most accurate and stable recognition of all three cell types, YOLOv8 seems to be a more balanced choice. However, in cases where accurate platelet detection is critical, YOLOv11 becomes a better candidate due to its higher efficiency in this category.

VII. Conclusions

The article investigates the problem of detection, localization and classification of biological objects in microscopic images using deep learning methods. As a training dataset, a dataset was used, automatically created on the basis of unannotated images using classical image processing algorithms and the k-means clustering algorithm, which allows avoiding manual labeling and significantly accelerating data preparation for training models.

The YOLOv8 and YOLOv11 architectures were used to solve the problem. Training and validation of the models showed that YOLOv8 provides higher accuracy and generalization, in particular in terms of metric accuracy, mAP@0.5 and mAP@0.5:0.95, compared to YOLOv11. In contrast, YOLOv11 showed a significantly higher processing speed, which makes it attractive for real-time tasks. Both models demonstrate high efficiency in solving the task, which indicates the suitability of modern YOLO object-detector architectures for medical image analysis. YOLOv8 proved to be a balanced solution that provides high-quality recognition of leukocytes and erythrocytes. At the same time, YOLOv11 demonstrated a noticeable improvement in the recognition of platelets, the smallest and most difficult to identify objects.

This suggests that model updates likely include optimizations that are better suited for small object recognition, which is especially valuable in medical scenarios where even insignificant details can have diagnostic weight.

Thus, it can be concluded that the use of automatically generated annotations in combination with modern deep learning architectures is an effective approach to solving biomedical image recognition problems, and the choice of a specific model (YOLOv8 or YOLOv11) depends on the accuracy or speed requirements in a particular case.

***Abstract*—To effectively address the challenge of expanding the range of paint and coating materials, a nanotechnology has been developed for producing lead-free pigments and fillers based on natural domestic montmorillonite-containing raw materials. This was achieved through the activation of red lump bentonite clays using various inorganic acids and sodium phosphate. A comparative analysis of activation methods was conducted. The influence of salt hydrolysis reactions via cations and anions on the efficiency of bleaching lump bentonite clays was studied. A resource- and energy-efficient technological process was modified to produce white fillers, organomodified bentonite, and pigments of various colors from the triphenylmethane series using an intercalation method. Formulations were calculated, and industrial paint and coating materials were developed for protecting metal, plastic, and wooden surfaces against corrosion. The physicotechnical properties of the materials and coatings were experimentally investigated, and their areas of application were identified and recommended. The mechanism of the anticorrosive action of a complex electrochemical corrosion inhibitor based on the synthesized pigments was studied.**

Keywords—paint and coating materials, redox reactions, hydrolysis, intercalation, resource conservation, fillers, pigments for paints and coatings

I. Introduction

Anisotropic solids with a layered structure are capable of forming intercalation compounds [1]–[3] through the insertion of various atoms, ions, and molecules (intercalants) into the interlayer galleries of crystalline matrices. Intercalation compounds are promising for use as catalysts in chemical reactions, electrodes in chemical power sources, solar cells, optical data storage media, semiconductor materials with variable mini-band electron spectra, materials for electrochromic display cells, and monochromators for neutron diffractometry. Layered aluminosilicates [4] are widely used as fillers for polymers [5, 6] and paint and coating materials (PCMs) [7]. This work demonstrates the possibility of synthesizing fillers and pigments based on montmorillonite – a layered aluminosilicate found in bentonite clays – using the intercalation method, and their application in paint and coating technologies to produce nanocomposite decorative and protective-decorative materials and coatings.

Pigments [8] and fillers in PCMs [9] perform multiple functions [10, 11], ranging from providing improved physico-mechanical properties and imparting specific color and decorative qualities to offering special properties such as anticorrosion [12].

With the adoption in Ukraine in 2021 of the technical regulation [14] restricting and prohibiting lead content in pigments and pigmented coatings, the range of available pigments has significantly narrowed. Particularly, a large number of anticorrosive pigments, such as lead silicochromate, lead primer chromate, basic lead carbonate (lead white), lead red lead, lead chromates, and lead-molybdate chromate, are now banned from use [15, 16]. The only anticorrosive pigment permitted under European standards remains zinc chromate [17].

Therefore, research aimed at expanding the range of lead-free pigments, especially anticorrosive, ones remains a pressing task.

Eurointegration processes shaping the development of the domestic paint and coatings industry are driving changes in the properties of modern coatings aimed at corrosion protection and improving the decorative appearance of products. These trends necessitate the development and implementation of innovative, environmentally safe paint and coating materials. Such materials include water-based (WB) and water-dispersion coatings utilizing water as a solvent [18], solvent-based (SB) materials with low volatile organic compound (VOC) [19] content [20], and powder coatings that comply with technical regulations limiting VOC content in coatings [21, 22]. Since 2021 [3], one of the key requirements for pigments and pigmented materials is the absence of lead, a heavy metal, in the composition of paint and coating materials.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

The aim of the work is the development of paint and coating materials for construction and industrial applications, as well as innovative technologies for their production using synthesized lead-free pigments and fillers. The scientific novelty of the work is also related to the modification of the redox method for obtaining white fillers [23] based on red lump bentonite clays and the intercalation method for synthesizing lead-free anticorrosive pigments and organomodified bentonite based on white bentonite fillers.

Achieving the objective of the work involves solving the following tasks:

- investigating the influence of hydrolysis processes on the redox mechanism of bentonite bleaching, and applying sodium phosphate salt in the activation method of red lump bentonite clay, which allows modifying the technology by removing the hydrolysis stage of water-soluble ferrous (II) sulfate and ferric (III) sulfate salts from the technological process;
- obtaining anticorrosive pigments and organomodified bentonite based on sodium bentonite by the intercalation method, free of lead in both raw materials and final products;
- developing formulations and innovative technologies with aspects of energy and resource saving to produce decorative water-soluble and water-dispersion paint and coating materials, anticorrosive primers, and enamel PCMs using synthesized pigments, fillers, and organomodified bentonite;
- investigating the physico-mechanical properties of the materials and formulating recommendations for the use of the developed materials.

II. Materials and Research Methods

Red lump bentonite clay was used as the raw material for the study, characterized by the following properties: montmorillonite content – 50 wt%, iron content expressed as Fe_2O_3 – 6.3 wt%, colloidal fraction – 93 %, water absorption – 5.6 units, and carbonate content calculated as $CaCO_3$ – 2.25 wt%. The chemical composition of the bentonite clay corresponds to the formula: $(Na,Ca)_{0.33}(Al,Mg)_2 Si_4O_{10}(OH)_2 \cdot nH_2O$.

For the modification of bentonite, solutions of alkyl dimethyl benzyl ammonium chloride (ADBC) and dimethyldi-n-octadecyl ammonium chloride (DDAC) (Alfa Chemical Co., Ltd.) were employed. Granulometric analysis of samples was conducted using a laser granulometer from Malvern. Samples of bentonite and their intercalation derivatives were studied by Fourier-transform infrared spectroscopy (FTIR) using a Specord IR-75 spectrophotometer with a recording scale of 150 mm/100 cm^{-1}. Samples were prepared by pressing into KBr pellets. X-ray phase analysis of samples was performed on a Dron-3 diffractometer using Cu Kα radiation and a nickel β-filter. Differential thermal analysis (DTA) of the organomodified bentonite was conducted using a Paulik–Paulik–Erdey derivatograph. Color characteristics of the investigated pigment and filler samples were determined using an NS 800 spectrophotometer.

III. Results and Discussion

With the aim of improving and modifying the technology for obtaining white bentonite fillers based on the redox mechanism [23], the activation stage involved treating red lump bentonite clay with aqueous solutions of sodium phosphate. It is known that the main requirements for fillers used in paint and coating materials are high whiteness degree, weather resistance, high dispersibility, low hardness, low cost and availability of raw materials, and minimal content of water-soluble substances.

Due to the red color of the lump clay caused by the iron content in the raw material amounting to 6.3 % calculated as Fe_2O_3, the bentonite bleaching technology involves activation of the clay with mineral hydrochloric or sulfuric acids to convert iron into water-soluble salts. The resulting water-soluble ferrous (II) chlorides and ferrous (II) sulfates, as well as ferric (III) chlorides and ferric (III) sulfates, undergo hydrolysis. The hydrolysis products of these salts with respect to the cation are ferrous (II) hydroxides and ferric (III) hydroxides. Due to oxidation reactions of ferrous (II) oxide in the presence of atmospheric oxygen, ferric (III) hydroxide of brownish color is formed, which causes a pink tint to appear in the color of the fillers. To prevent and inhibit the hydrolysis and redox reactions leading to the formation of ferric (III) hydroxide, the reaction is carried out in an acidic environment at pH ≤ 1–3. Low pH values shift the chemical equilibrium according to Le Chatelier's principle toward the formation of the initial substances, namely ferrous (II) sulfates and chlorides. To prevent the progression of oxidation processes increasing the oxidation state of Fe^{2+} cations to Fe^{3+}, the bentonite bleaching technology requires mandatory addition of reducing agents to the reactor-activator: iron scrap at the first stage and metallic zinc at the final stages of bleaching. The present work proposes a modification of the technology for producing bleached bentonite fillers by treating the clay suspension with sodium phosphate. The advantages of using sodium phosphate include, firstly, the ability to alter the pH of the medium due to hydrolysis of this salt by the anion and the formation of solutions with pH ≥ 7. The cation exchange reactions using sodium phosphate can be schematically represented as follows:

$$Na_3PO_4 + Mnt\text{-}(Fe^{2+}/Ca^{2+}/Mg^{2+}) \leftrightarrow$$

$$\leftrightarrow Mnt\text{-}Na^+ + (Fe^{2+}/Ca^{2+}/Mg^{2+})_3(PO_4)_2\downarrow, \quad (1)$$

$$Na_3PO_4 + Mnt\text{-}(Fe^{3+}) \leftrightarrow Mnt\text{-}Na^+ + Fe^{3+}PO_4\downarrow. \quad (2)$$

Both reactions are strongly shifted to the right due to the formation of precipitates of water-insoluble salts of ferrous (II) and ferric (III) ions, as well as calcium and magnesium phosphates.

In this work, X-ray phase analysis was used to identify montmorillonite in the bentonite composition and to establish the occurrence of intercalation processes during the synthesis of organo-modified montmorillonite. The advantages of treating clay with sodium phosphate salts, apart from eliminating the hydrolysis stages of cations that occur when mineral acids are used at the activation stage and the reduction stages, include the conversion of the calcium-magnesium form of montmorillonite into the sodium form. Experimental confirmation of the intercalation and cation exchange processes was obtained through X-ray phase analysis of the initial lump clay samples and the samples obtained after treatment with sodium phosphate. According to X-ray phase

analysis data, the investigated sample exhibits a rather wide range of distances between the silicate layers of the clay, with an average value of 15.3 Å, which is characteristic of the calcium form of bentonite. After purification and treatment of the clay with sodium phosphate, the montmorillonite predominantly transforms into the sodium form. The interlayer spacing in sodium-form montmorillonite is 12.8 Å. Calculations were performed using the Bragg-Wulff equation. As a result of the X-ray phase analysis, the identity of the structure of the studied montmorillonite samples, a layered mineral predominant in the bentonite composition, with the montmorillonite structure was established. The position of the reflections on the montmorillonite diffractogram in the low-angle region corresponds to the basal interplanar spacing of 15.3 Å characteristic of montmorillonite. The sample of bleached, neutralized, and organo-modified bentonite with ADBC and DDAC shows intense broad reflections in the low-angle range with d = 18.47 Å and d = 18.7 Å, respectively, which is an indication of the formation of an intercalated structure of the organo-modified bentonite. The broadening of the low-angle peak may indicate the presence of exfoliated, delaminated structures in the intercalation compounds within the «montmorillonite-ADBC" and "montmorillonite-DDAC» systems. The hydrolysis reactions of sodium phosphate (pH ≥ 7) can be described by the following molecular reactions:

stage I of hydrolysis:

$$Na_3PO_4+HOH\leftrightarrow Na_2HPO_4+NaOH, \quad (3)$$

stage II of hydrolysis:

$$Na_2HPO_4+HOH\leftrightarrow NaH_2PO_4+NaOH, \quad (4)$$

stage III of hydrolysis:

$$NaH_2PO_4+HOH\leftrightarrow H_3PO_4+NaOH. \quad (5)$$

The protective mechanism of iron phosphates may be associated with the formation of a complex acid according to the following chemical reaction:

$$Fe_3(PO_4)_2+4H_2O=[Fe_3(PO_4)_2(H_2O)_2(OH)_2]^{2-}+2H^+, \quad (6)$$

which reacts with iron ions on the metallic surface at microanodes forming a complex corrosion inhibitor: $[Fe_3(PO_4)_2(H_2O)_2(OH)_2]Fe$, reducing the anodic area of micro-galvanic elements on the metal surface and inhibiting electrochemical corrosion processes.

The complex inhibitor's outer coordination sphere may include a carboxyl group -*COOH* from the film-forming agent instead of one water molecule, specifically:

$$Fe_3(PO_4)_2+3H_2O+\text{-}COOH=$$
$$=[Fe_3(PO_4)_2(H_2O)(COOH)(OH)_2]_2. \quad (7)$$

Thus, the technological process of bleaching red lump bentonite clay by treatment with sodium phosphate consists of the following stages: formation of an aqueous suspension of lump bentonite clay; filtration and removal of mechanical impurities; sedimentation followed by decantation to remove water-soluble substances; cation exchange using sodium phosphate; drying using a jet dryer at temperatures below 40 °C with particle size classification up to 50 μm. At this stage, as a resource-saving measure, water recovery is provided for reuse as return water in the first stage of the technological process of forming the aqueous clay suspension.

To obtain organomodified bentonite, it is necessary to modify the above technological process by adding an intercalation stage of montmorillonite with quaternary ammonium salts from aqueous solutions after the third stage and before the fourth stage drying of the finished product. It should be noted that the developed technological process using sodium phosphate allows obtaining not only white fillers but also imparts anticorrosive properties due to the presence in their chemical composition of water-insoluble iron (II) phosphates, iron (III) phosphates, calcium phosphates, and magnesium phosphates.

The intercalation and cation exchange reactions using sodium phosphate and ADBC can be schematically represented as follows:

$$Mnt\text{-}Na_{0.33}^{+}+_d[C_6H_5(CH_2)(CH_3)_2RN]^+Cl^-\leftrightarrow$$
$$\leftrightarrow Mnt[C_6H_5(CH_2)(CH_3)_2RN]_d^{+}+0.33NaCl;\ R=C_{16}\text{–}C_{18}. \quad (8)$$

The intercalation and cation exchange reactions using sodium phosphate and DDAC can be schematically represented as follows:

$$Mnt\text{–}Na_{0.33}^{+}+_d[(CH_3(CH_2)_{17})_2(CH_3)_2N]^+Cl^-\leftrightarrow$$
$$\leftrightarrow Mnt[(CH_3(CH_2)_{17})_2(CH_3)_2N]_d^{+}+0.33NaCl. \quad (9)$$

For the purpose of identifying and confirming the purity of raw materials, as well as determining the nature of interactions between quaternary ammonium salts, triphenylmethane dye molecules, and montmorillonite, the synthesized pigments and fillers were studied using spectral analysis methods in the visible and infrared regions of the spectrum. The studies in the visible region were conducted to determine colorimetric characteristics.

The intercalation and cation exchange reactions involving ADBC and malachite green dye molecules can be schematically represented as follows:

$$Mnt\text{-}Na_{0.33}^{+}+_d[C_6H_5(CH_2)(CH_3)_2RN]^+Cl^-+$$
$$+_y[C_{23}H_{25}NN]^+Cl^-\leftrightarrow$$
$$\leftrightarrow Mnt[C_6H_5(CH_2)(CH_3)_2RN]_d^{+}[C_{23}H_{25}NN]_y^{+}$$
$$+0.33NaCl. \quad (10)$$

The intercalation and cation exchange reactions involving DDAC and malachite green dye molecules can be schematically represented as follows:

$$Mnt\text{-}Na_{0.33}^{+}+_d[(CH_3(CH_2)_{17})_2(CH_3)_2N]^+Cl^-+$$
$$+_y[C_{23}H_{25}NN]^+Cl^-\leftrightarrow$$
$$\leftrightarrow Mnt[(CH_3(CH_2)_{17})_2(CH_3)_2N]_d^{+}[C_{23}H_{25}NN]_y^{+}+$$
$$+0.33NaCl. \quad (11)$$

The intercalation and cation exchange reactions involving ADBC and rhodamine C dye molecules can be schematically represented as follows:

$$Mnt\text{-}Na_{0.33}^{+}+_dC_{28}H_{31}O_3ClN_2+_yC_{27}H_{50}N^+Cl^-\leftrightarrow$$
$$\leftrightarrow Mnt(C_{28}H_{31}O_3NN)^+_d(C_{27}H_{50}N)^+_y]+0.33NaCl. \quad (12)$$

The intercalation and cation exchange reactions involving DDAC and rhodamine C dye molecules can be schematically represented as follows:

$$[(CH_3(CH_2)_{17})_2(CH_3)_2N]^+Cl^-+Mnt\text{-}Na_{0.33}+$$

$$+_d[(CH_3(CH_2)_{17})_2(CH_3)_2N]^+Cl^- +_y C_{27}H_{50}N^+Cl^- \leftrightarrow$$
$$\leftrightarrow Mnt[(CH_3(CH_2)_{17})_2(CH_3)_2N]_d^+(C_{27}H_{50}N)^+_y] +$$
$$+0.33NaCl. \quad (13)$$

The color characteristics of the synthesized samples were investigated as follows: sample №1 (white fillers): color coordinates in the XYZ system: X=46; Y=55; Z=63; chromaticity coordinates: x=0.28; y=0.34; Y=55; color coordinates in the CIELAB system: L=79.25; A=2.04; B=7.98; dominant wavelength λ=473 nm; color purity p=7 % – determined from the chromaticity diagram.

For samples of Mnt treated with sodium phosphate and ADBC (№2), the following color parameters were determined: X=65; Y=69; Z=67; L=86.68; A=1.94; B=6.69; λ=498 nm; p=7%.

For samples of Mnt modified with ADBC and malachite green dye (№3): X=27; Y=34; Z=38; L=64.72; A=18.75; B=1.27; λ=508 nm; p=21%.

For samples of Mnt modified with ADBC and rhodamine C dye (№4): X=35; Y=26; Z=43; L=57.95; A=38.99; B=18.81; λ=530 nm; p=28%.

Samples of green and red pigments were obtained at different concentrations of malachite green and rhodamine C – 0.01 M and 0.05 M – which affected the color characteristics of the materials. With an increased concentration of malachite green, the color purity increased from 21 % for sample №3 to 30 %, while increasing the concentration of rhodamine C raised the color purity from 28 % for sample №4 to 36 %. A shift in the dominant wavelength was observed from 508 to 521 nm for malachite green compounds, and from 530 to 610 nm for rhodamine C. Thus, increasing the dye concentration allows obtaining pigments with different color intensities within economically feasible limits. It should be noted that the low color purity values for samples bleached using sodium phosphate indicate the complete binding of iron cations as a result of activating the original red lump clay. The determined physical and technical properties of the fillers after treatment of bentonite with sodium phosphate are as follows: first-order oil absorption – 53.4 g/100g; coverage – 458 g/m²; density – 2700 kg/m³; water-soluble substances–absent; pH of the aqueous extract – 7.

Laser diffraction as a method for analyzing the granulometric composition of organomodified bentonite was applied in this work to analyze the granulometric composition of the obtained pigments, fillers, and organomodified bentonite.

As a result of a comparative analysis of the properties of the original lump clay samples and organomodified bentonite ADBC, an increase in homogeneity from 0.784 to 1.804 was established, along with an increase in the specific surface area of the samples from 323.3 to 1175 m²/kg. The surface modification of the bleached bentonite led to an increase in homogeneity to 1.804 and an increase in the specific surface area to 1175 m²/kg. The obtained results correspond well with the expected changes in the crystalline structure of the layered aluminosilicates transformed at various stages of the technological process. Indeed, the processes of washing out water-soluble substances, activation, and organomodification of the natural raw material are associated not only with the peptization of aluminosilicate particles in aqueous solutions but also with simultaneous intercalation reactions of quaternary ammonium salt molecules into the interlayer galleries of montmorillonite. It is known that the intercalation process leads to the destruction of layer planes and the formation of smaller particles of the inorganic matrix. Studies of organobentonite based on ADBC and DDAC and the initial bentonite indicate a sharp decrease in the effective particle diameter of the main fraction to 10 μm at the final stages of the technological process. The particle size reduction during modification is related to exfoliation processes, i.e., the delamination of the aluminosilicate structure into individual planes corresponding to the two-dimensional layers of the montmorillonite crystalline structure. Intercalation of montmorillonite, as with other layered matrices, causes a decrease in the particle size of the matrix, which is manifested as a low-angle halo on X-ray diffraction patterns of the intercalated structures. Thus, the conducted granulometric analysis of the transformed natural bentonite samples aimed at obtaining organomodified bentonite for paint and coating materials indicates the consistency of the obtained experimental results with the theoretical foundations of intercalation transformations of layered inorganic matrices. Infrared spectroscopy studies of the organomodified bentonite were performed to establish the mechanism of interaction between quaternary ammonium salts and the inorganic matrix.

The analysis of the IR spectra of the studied bentonite (red lump clay) and organomodified bentonite allowed the assignment of the main valence and deformation vibrations, which are presented in Table 1, 2.

TABLE I. WAVENUMBERS (N, CM⁻¹) OF ABSORPTION MAXIMA IN THE IR SPECTRA OF BENTONITE

Structural group	Stretching vibrations, cm⁻¹	Bending vibrations, cm⁻¹
Al-Al-OH	3628	
Al-Fe³⁺-OH	3590 – broad band shoulder at max 3435.1	875.3
Fe³⁺-Fe³⁺-Mg	3565 – broad band shoulder 3435.1	
H₂O	3435.1	1644.8; 1455.9
Si-O (tetrahedron)	1034.5	519

Si-O-Al		467

In the IR spectrum of organomodified montmorillonite ADBC, vibrations of the CH_3 group attached to the nitrogen heteroatom appear as intense bands at 2853.3 cm^{-1} and 2924.9 cm^{-1}, corresponding to symmetric and asymmetric stretching vibrations of the methyl group; deformation vibrations of the methyl group are observed at 1416.9 cm^{-1} and 1378.3 cm^{-1}. These bands may be attributed to vibrations of the quaternary nitrogen atom. A characteristic feature indicating the formation of a new intercalation compound is the appearance of a new band at 3064.1 cm^{-1}, which corresponds to vibrations of the quaternary nitrogen atom. The emergence of new vibration bands at 702.5 cm^{-1} and 728.7 cm^{-1} in the spectrum of organomodified bentonite, associated with pendulum-type deformation vibrations of the (-CH_2-) groups, also indicates the occurrence of the intercalation reaction of ADBC into the interlayer spaces of montmorillonite. The nature of the changes observed in the infrared spectra of bentonite and organomodified bentonite allows us to conclude that the intermolecular interactions during intercalation are of a donor-acceptor type.

Differential thermal analysis (DTA) was performed on samples of bentonite, organomodified bentonite, free films based on pentaftalic oligomer, and pentaftalic oligomers modified with organobentonites. Curing by the oxy-polymerization mechanism was carried out under identical conditions at 80 °C for two hours using *Co*, *Mn*, *Ba* siccative as a catalyst. The content of organobentonites was 1%. Thermograms of the five studied samples were analyzed. TG curves in the temperature range of 100–107 °C showed a mass loss of 1.43 % and 1.58 % for Mnt-ADBC and Mnt-DDAC samples, respectively, which can be attributed to the loss of adsorbed water. The maxima on the DTG curves at these temperatures indicate the maximum rate of water loss from the organobentonite samples. Endothermic effects were observed on the DTA curves in the specified temperature range. The second peak on the DTG curves of the organobentonite-containing samples occurs at 285 °C and 273 °C for Mnt-ADBC and Mnt-DDAC samples, respectively, corresponding to the thermal degradation of the modifiers – quaternary ammonium salts. It is noteworthy that the thermal stability of the pentaftalic oligomer, which decomposes up to 260 °C, increases in compositions with organobentonites to 270–285 °C. Another important observation is the reduction in the total mass loss of the organobentonite-modified samples to 38 % and 33 %, which indicates the degradation of intercalation phases rather than surface-adsorbed molecules of ADBC and DDAC.

Thus, organobentonites exhibited a minimal amount of adsorbed water in the temperature range of 20–120 °C, approximately 1–2 %, compared to 7 % for the original clay. The presence of a significant endothermic effect in the temperature range of 200–350 °C, accompanied by a mass loss of 15–20 % for organobentonites, is associated with the degradation of the organic matter. The results of the thermal analysis indicate that, based on a comparative assessment of properties, the organobentonite based on Mnt-ADBC is preferable.

The study involved the application of organomodified bentonites, fillers, and lead-free anticorrosive pigments as components of pigmented coating materials.

Coating materials were developed based on the synthesized fillers, pigments, and organomodified bentonites. In the formulations, the pigment portion was replaced with the new bentonite fillers and pigments. The physicochemical properties of materials AU-122 I and facade water-dispersion paints are presented in Tables 3 and 4.

TABLE III. PHYSICOTECHNICAL PROPERTIES OF ENAMELS AND COATINGS WITH HIGH NON-VOLATILE CONTENT (TU U 20.3-34328580-001:2020)

Measured Parameter	AU-122 I Standard	Enamel with Mnt-ADBC
Conditional viscosity at (20±0.5)°C, s, not less than (DSTU ISO 2884-2)	60-160	150
Degree of dispersion, μm, not more than (DSTU ISO 1524)	45	45
Drying time to stage 3 at (20±2)°C, hours, not more than (DSTU ISO 9117-1)	3	2.5

According to the annexes of regulation TU U 20.3-34328580-001:2020, the primer-enamel AU-122 I is classified as a finishing coating material for both interior and exterior works on wooden and metal surfaces. In accordance with TU U, the VOC content should be ≤ 300 g/L. The new material contains VOCs at 294 g/L, whereas the standard formulation material contains 523 g/L. The purpose of this VOC limit is to reduce air pollution caused by VOCs' contribution to the formation of tropospheric ozone.

The AU-122 I primer enamel is a suspension of weather-resistant and anticorrosive pigments and fillers in solutions of organic oligomers, supplemented with additives to provide barrier and anticorrosive protection of surfaces and ensure optimal curing speed. The AU-122 I primer enamel is recommended for use in integrated systems of industrial coating applications on ferrous metal surfaces.

TABLE IV. PHYSICOTECHNICAL PROPERTIES OF WATER-DISPERSION FACADE PAINT (TU U 20.3-34328580-009:2021)

A comparative analysis of the properties of materials and coatings, formulated using standard recipes and those

incorporating bleached bentonite fillers, organo-modified bentonites, and lead-free anticorrosive pigments obtained through the treatment of red granular bentonite clay with sodium phosphate, confirms the complete compliance of the AU-122 I primer enamel and the water-dispersion facade paint, as well as the coatings based on them, with the requirements of TU U 20.3-34328580-001:2020 and TU U 20.3-34328580-009:2021, respectively.

IV. Conclusion

Research was conducted to replace mineral acids during the activation stage of granular bentonite clay with sodium phosphate. This approach aims to prevent the formation of hydrolytic wastewater and reduce water consumption for washing away water-soluble salts.

It was established that the use of sodium phosphate, which hydrolyzes to an anion with a pH ≥ 7, enhances the environmental safety of the technology and facilitates the production of Na-form bentonite for obtaining organo-modified bentonite.

The organo-modification of Na-form bentonite was performed using ADBC and ADBC, which are quaternary ammonium salts.

New lead-free anticorrosive pigments were synthesized by the intercalation method, employing quaternary salts of triphenylmethane dyes.

The properties of fillers, organo-modified bentonites, and lead-free pigments were investigated using physicochemical analysis methods. The aim was to identify the purity of the initial substances, preserve the layered structure of aluminosilicate (montmorillonite), and study the interaction of montmorillonite with sodium phosphate, ADBC and ADBC, malachite green, and rhodamine C.

The paint and technical properties of the processed granular red bentonite clay – pigments and bentonite fillers – were determined. Their values fully comply with the technical, economic, and environmental requirements for pigments and fillers used in coatings and paints.

Coating materials, including AU-122 I primer enamel and water-dispersion facade paint, were developed. These materials utilize the synthesized pigments, fillers, and functional additives in the form of organobentonites.

***Abstract*— High-density alumina ceramics are widely used in many fields of science and technology, including as electrical insulating elements of various electrophysical installations. The influence of technological factors on the properties of slips and samples of alumina ceramics made of super-reactive alumina grades A and B has been investigated. It is found that introducing a dispersing additive in the amount of 0.4 % in the slips of these aluminas reduces their dynamic viscosity to minimum values, improving the fluidity of the slips. Slips with the optimal amount of dispersing additive have high sedimentation stability. It is established that increasing the moisture content of slips from alumina grades A and B decreases their dynamic viscosity. The optimum moisture content (20 %) of slips intended for the pouring method of molding has been determined. It is established that the use of super-reactive alumina of A and B grades for the manufacture of products by slip casting into gypsum molds provides the production of high-density alumina ceramics. Based on the research results, the technology of high-density alumina ceramics by the slip casting method into gypsum molds was improved, and the raw material base for its production was expanded.**

Keywords*— *alumina ceramics, super-reactive alumina, slip casting, dispersing additive, dynamic viscosity, sedimentation stability, properties

I. Introduction

Specially dense alumina ceramics are widely used in various fields of science and technology due to their chemical inertness, high dielectric and strength properties. Alumina ceramic products are used as structural, high-temperature, electrical insulating elements and units of electrophysical equipment, with a service temperature of up to 1850 °C [1–3]. Specially dense alumina ceramics with content of Al_2O_3 99.4–99.7 %, Na_2O 0.005–0.01 %, MgO 0.12–0.15 %, SiO_2 0.04–0.1 %, open porosity close to zero have dielectric loss angle tangent at 20 °C 5×10^4, dielectric permittivity 9.8–9.9, breakdown voltage 18–22 kV/mm [1–4]. An increase in the Na_2O or SiO_2 amount in alumina ceramics leads to a several-fold decrease in the breakdown voltage and an increase in dielectric losses [1]. The particle size of the initial raw material, its MgO content, technological parameters of molding, and firing mode of products influence the crystal size, the presence of defects in the structure, and the density of ceramics, which affects its properties. Therefore, in the manufacture of high-density alumina ceramics, great attention is paid to the selection and preparation of raw materials, as well as the development of technological parameters of molding and firing.

JSC “URIR named after A. S. Berezhnoy” has carried out research and development work on the creation and improvement of alumina ceramic products technology for many years [1–3]. The technology of highly refractory alumina ceramic products, which are made by various methods, has been developed and introduced. The slip casting method into gypsum molds is the most widely used due to its simplicity, low cost of the equipment and tooling, and the possibility of manufacturing products of various shapes and sizes.

In recent years, companies producing raw materials have offered especially pure super-reactive alumina, which can be used without preliminary preparation, for the production of alumina ceramics. The Institute has developed technological parameters of slip casting of alumina ceramics with the content of $Al_2O_3 \geq 99.5$ %, MgO ≤ 0.1 %, $SiO_2 \leq 0.1$ %, $Fe_2O_3 \leq 0.05$ %, open porosity ≤ 0.8 % with the use of alumina with specific surface area 6–10 m^2/g, average particle size 0.2–1.5 microns and bulk density 900 kg/m^3 as a raw material. The compositions of aqueous alumina slips intended for the drain method of molding, used for the manufacture of products with a wall thickness of 1–3 mm, and the pour method — for the manufacture of products with a wall thickness of 4–5 mm and more, as well as products with a continuous section, have been determined [5–8].

At the same time, the research on super-reactive alumina of new grades, as well as the influence of technological factors on the properties of slips and samples of these alumina to determine the possibility of their use in the technology of high-density alumina ceramics by the method of slip casting, is of scientific and practical interest.

II. Research Methods

To perform the research, alumina grades A and B produced by a German company, a dispersing additive (aqueous solution of ammonium salt of acrylic copolymer), and distilled water were used as raw materials.

According to the manufacturer's data, alumina grades A and B belong to the class of super-reactive monomodal alumina with the content of Al_2O_3 99.7 %, α-Al_2O_3 98 %, specific surface area ~ 7 m^2/g, bulk density ~ 950 kg/m^3, and average particle size 1.0 micron for alumina grade A and 0.8 micron for alumina grade B.

Because many alumina ceramic products are made with the pouring method, the research was carried out using this casting method.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

The feasibility of introducing a dispersing additive into the slip to improve its rheological characteristics has been previously shown, and its optimum amount has been determined for the manufacture of products by the pouring method [6].

In this work, we investigated the effect of dispersing additives on the rheological properties (dynamic viscosity and sedimentation stability) of slips from alumina of new grades. For this purpose, aqueous slips from alumina grades A and B were prepared with a moisture content of 25 %, in which the additive was introduced in different amounts.

To study the dynamic viscosity of slips depending on their moisture content and storage time, slips were prepared by adding different amounts of alumina to distilled water. The slips containing the optimum amount of dispersing additive were used. The moisture content of the slips was 15 %, 20 %, and 25 %. All the slips were thoroughly mixed, filtered through a sieve, and then stored in a sealed container. The ambient temperature was 20 °C. The density of the slips was determined as the ratio of their mass to volume.

Moisture content of the slips was calculated by the formula:

$$W_{sl} = (g_0 - g_1) \times 100\ \% / g_0 \qquad (1)$$

where g_0 is the mass of the wet slip sample, g, and g_1 is the mass of the dried slip sample, g [9].

The dynamic viscosity of the slip was determined on a Brookfield LVDV-II + Pro digital viscometer at a spindle speed of 100 rpm. [10].

To determine the slip sedimentation stability, the slip was poured into a glass measuring cylinder, which was placed in a sealed container and kept for 14 days. During the slip storage, the volume of the separated liquid phase from the suspension was periodically noted visually. The coefficient of slip sedimentation stability was determined by the formula:

$$U = (V_{sl} - V) / V_{sl} \qquad (2)$$

where V_{sl} is the slip volume, cm^3, and V is the separated liquid phase volume, cm^3 [9].

Samples were made by the slip casting method into gypsum molds, then dried at 20 °C for 1–2 days, and at 110 ± 10 °C to constant weight. The samples were fired at a temperature of 1580 °C with a holding time of 6 hours in a batch gas-flame furnace.

The determination of the main property parameters was carried out according to Ukrainian/ISO standards. The cold crushing strength was determined according to DSTU ISO 10059-1:2018; the bending strength determination (three-point) was carried out according to DSTU ISO 5014:2018. The apparent density and open porosity of fired samples were determined according to DSTU ISO 5017:2014 (ISO 5017:1998, IDT).

III. Discussion of the Results

Determination results of the dynamic viscosity of the slips from alumina of A and B grades, depending on the content of dispersing additive, are presented in Table 1.

TABLE I. Dynamic Viscosity of Slips from Alumina Brands A and B with Different Content of Dispersing Additive

Alumina grades	Dispersing additive content, %						
	0	*0.1*	*0.2*	*0.3*	*0.4*	*0.5*	*0.6*
	Dynamic viscosity of slips, mPa·s						
A	1020	800	500	90	70	80	100
B	810	520	270	130	110	120	145

Table 1 shows that the dynamic viscosity of slip from alumina of grades A and B without a dispersing additive has maximum values. The influence of dispersing additive is based on its ability to envelop alumina particles, separating the aggregates formed by them, increasing the slip flowability. With the introduction of 0.1 % of the additive, the dynamic viscosity of the slips significantly decreases, but remains high enough and is 800 mPa·s for the slip of alumina grade A and 520 mPa·s for the slip of alumina grade B. When the content of dispersing additive is increased up to 0.4 %, the dynamic viscosity of the slips continues to decrease, reaching minimum values of 70 mPa·s and 110 mPa·s, respectively. Further increase in the content of dispersing additive in the slips leads to a slight increase in their dynamic viscosity, which is inexpedient, so the amount of dispersing additive of 0.4 % is optimal.

Determination results of the sedimentation stability coefficient of slips from alumina of grades A and B containing 0.4 % of dispersing additive are shown in Fig.

After storage in a sealed container for 14 days, the slips were mechanically stirred again, and their sedimentation stability coefficient was determined.

It follows from Fig. that at holding time of slip from alumina of grades A and B within 1 day, all the slips are characterized by a fairly high sedimentation stability, which with increasing storage time up to 5 days decreases slightly, and with increasing holding time up to 14 days decreases by 10–20 % due to the separation of the slip into solid and liquid phases. The slip from alumina of grade B has a slightly higher sedimentation stability than that from alumina A grade. It is probably due to the greater dispersibility of alumina B grade.

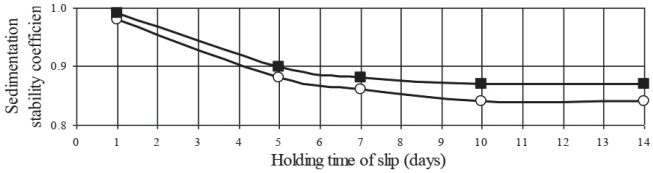

Fig. Sedimentation stability coefficient of slips from new brands of aluminas: ○ — slip from brand A alumina, ■ — slip from brand B alumina

It was found that after 1 day, the volume of a separated liquid phase and the coefficient of sedimentation stability corresponded to similar values before mixing. This fact indicates that the introduction of a dispersing additive in the optimal amount provides, in addition to satisfactory rheological characteristics, also the stability of the slip, which is important in the technology of products by slip

casting into gypsum molds, especially in the manufacture of ceramic products by the pouring method.

Thus, it was found that introducing 0.4 % of the dispersing additive in the slips from super-reactive alumina of grades A and B reduces their dynamic viscosity to minimum values and improves their fluidity. The slips from alumina of grades A and B with the optimal amount (0.4 %) of dispersing additive are characterized by high sedimentation stability.

The study also investigated the dynamic viscosity of alumina-based slips of A and B grades, depending on their moisture content and holding time (Table 2).

TABLE II. DYNAMIC VISCOSITY OF ALUMINA-BASED SLIPS CONTAINING 0.4 % OF DISPERSING ADDITIVE AS A FUNCTION OF MOISTURE CONTENT AND HOLDING TIME

Alumina grades	Holding time, hours					
	0	*4*	*8*	*24*	*48*	*56*
Moisture content 15%						
A	782	740	692	648	623	620
B	833	771	718	670	647	644
Moisture content 20%						
A	550	510	460	400	380	378
B	610	555	502	423	402	399
Moisture content 25%						
A	433	388	365	345	317	315
B	443	403	387	363	328	326

As follows from Table 2, the dynamic viscosity of all the slips begins to decrease almost immediately after their preparation, and this process continues until about 24 hours of holding time. At further increase in the holding time over 24–48 hours, the values of dynamic viscosity practically do not change. This character of change in dynamic viscosity indicates that even in freshly prepared slips, there are aggregates with a fragile structure of alumina particles, which, with increasing holding time, spontaneously collapse. As a result, there is a decrease in the dynamic viscosity of the slips, as it releases bound water in them and increases the number of dispersed particles that are not bound in aggregates. The optimum holding time of slips should be considered 24 hours, when their dynamic viscosity becomes minimal, and consequently, their fluidity improves. The fact that after holding time for more than 48 hours, the dynamic viscosity of the slips remains minimally low indicates their high manufacturability and the possibility of using them for the manufacture of products. The dynamic viscosity of alumina-based slips of grade B is slightly higher than that of alumina-based slips of grade A, which can be explained by the fact that it consists of more dispersed particles. Increasing the moisture content of slips from 15 % to 20 % leads to a significant decrease in their dynamic viscosity. Further increase in the moisture content of these slips up to 25 % contributes to decreasing their dynamic viscosity insignificantly. This is apparently because the slip moisture content of 20 % is sufficient for the spontaneous destruction of alumina particle aggregates, and an increase in the number of unbound particles covered with solvate shells, leading to a decrease in the dynamic viscosity of the slip.

Determination results of the main properties of alumina ceramic samples made of alumina-based slips of grades A and B with different moisture content before and after firing at a temperature of 1580 °C with a holding time of 6 hours are shown in Tables 3 and 4, respectively.

TABLE III. MAIN PROPERTIES OF SAMPLES MADE OF ALUMINA-BASED SLIPS OF GRADE A WITH DIFFERENT MOISTURE CONTENT BEFORE AND AFTER FIRING AT A TEMPERATURE OF 1580 °C

Sample properties	Moisture content, %		
	15	*20*	*25*
Properties of dried green			
Apparent density, g/cm^3	2.17	2.20	2.15
Cold crushing strength, N/mm^2	0.7	1.0	0.6
Properties of samples after firing at 1580 °C with a holding time of 6 hours			
Apparent density, g/cm^3	3.87	3.90	3.85
Open porosity, %	0.7	0.5	0.9
Change linear dimensions at firing (shrinkage), %	–23	–23	–25
Bending strength, N/mm^2	175	190	160

TABLE IV. MAIN PROPERTIES OF SAMPLES MADE OF ALUMINA-BASED SLIPS OF GRADE B WITH DIFFERENT MOISTURE CONTENT BEFORE AND AFTER FIRING AT A TEMPERATURE OF 1580 °C

Sample properties	Moisture content, %		
	15	*20*	*25*
Properties of dried green			
Apparent density, g/cm^3	2.16	2.18	2.13
Cold crushing strength, N/mm^2	0.6	0.8	0.5
Properties of samples after firing at 1580 °C with a holding time of 6 hours			
Apparent density, g/cm^3	3.83	3.86	3.80
Open porosity, %	1.0	0.7	1.2
Change linear dimensions at firing (shrinkage), %	–26	–26	–27
Bending strength, N/mm^2	180	200	170

As follows from Tables 3 and 4, the samples made of slips with a moisture content of 20 % have the highest property values. The samples made of slips with moisture content of 15 % have lower apparent density of green, which is explained by the rapid gain of the shard walls, which prevents the further impregnation of water from the slip into the gypsum mold, and, thus, the formed casting has a greater number of pores and is less dense and less strong. The samples made with 25 % moisture content also have a lower apparent density of the green due to the greater volume of water that must be absorbed from the slip into the gypsum mold, which leads to a decrease in the shard's gain speed, and the casting becomes less strong and dense. The optimum should be considered as the moisture content of 20 %. This is because the samples from such slips have the highest properties (open porosity less than 0.8 %, i.e., they are particularly dense). At the same time, the samples from alumina of grade A have a slightly higher apparent density and lower shrinkage at firing than the samples from alumina of grade B, with similar bending strength values. This can be explained by denser shard formation during casting the slip from alumina of grade A due to its lower dynamic viscosity and better fluidity, and further obtaining denser fired samples with fewer closed pores in the structure. Thus, both A and B grade alumina can be used in the technology

of alumina ceramics by slip casting into gypsum molds, but using alumina of grade A is preferable.

Thus, as a result of studies of the technological factors' influence on the properties of slips and samples of alumina ceramics from super-reactive alumina of grades A and B, the optimum amount of dispersing additive (0.4 %) introduced into the slips and the optimum moisture content of slips (20 %) were determined. The necessity of holding time freshly prepared slips to reduce their dynamic viscosity for 24 hours before molding products was shown. It was established that the use of super-reactive alumina of A and B grades for the manufacture of products by the method of slip casting into gypsum molds provides the obtaining of high-density alumina ceramics with open porosity less than 0.8 %, apparent density 3.86–3.90 g/cm^3, and bending strength 190–200 N/mm^2. It was shown that using alumina grade A compared to alumina grade B is preferable.

Detailed studies of the dielectric properties of the obtained ceramics will be carried out in further work. However, given their chemical composition, physical and mechanical properties, it can be confidently stated that their dielectric properties correspond to those of alumina ceramics obtained from traditional materials, namely dielectric loss angle tangent at 20 °C 5×10^4, dielectric permittivity 9.8–9.9, and breakdown voltage 18–22 kV/mm.

The research results show that the technology for producing high-density alumina ceramics using the slip casting method in gypsum molds has been improved, and the range of raw materials used in its production has been expanded.

The alumina ceramics obtained as a result of the research can be used as insulators for high-voltage equipment, heating element components (where high temperature resistance and electrical insulation are required), vacuum electronics components, in sensors operating at high temperatures, and for the manufacture of substrates and housings for electronic components, etc.

IV. Conclusions

The influence of technological factors on the properties of slips from super-reactive alumina of new grades A and B and alumina ceramics samples made from them has been investigated. The optimum quantity of dispersing additive (0.4 %) in slips from these aluminas, introduction of which leads to a reduction of the dynamic viscosity of slips to minimum values, has been determined. It has been established that alumina slips from alumina of grades A and B with the optimal dispersing additive amount are characterized by high sedimentation stability.

The necessity of holding time freshly prepared slips from alumina of grades A and B for 24 hours to reduce their dynamic viscosity before molding products was shown. It was found that increasing the moisture content of alumina slips decreases their dynamic viscosity. The optimum moisture content of slips (20 %) intended for the pouring method of molding was determined.

The main properties of samples from alumina of grades A and B before and after firing at a temperature of 1580 °C have been determined. It was established that the use of super-reactive alumina of grades A and B for the manufacture of products by the method of slip casting into gypsum molds provides the production of high-density alumina ceramics with open porosity less than 0.8 %, apparent density of 3.86–3.90 g/cm^3, and bending strength of 190–200 N/mm^2. It was shown that using alumina grade A compared to alumina grade B is preferable.

Based on the research results, the technology for producing high-density alumina ceramics using the slip casting method in gypsum molds has been improved, and the range of raw materials used in its production has been expanded.

An Investigation into Autoencoder-Based Feature Extraction for Electromyographic Signal Classification

Tatyana Zhemchuzhkina
Department of Biomedical Engineering
Kharkiv National University of Radio Electronics
Kharkiv, Ukraine
ORCID: 0000-0001-8884-5099

***Abstract*—The work is devoted to the study of methods for automated feature extraction from electromyographic signals for their classification in diagnostic problem. The relevance of the study is due to the need to improve the accuracy of differential diagnostics of low back pain, where traditional spectral and statistical features do not always provide reliable classification. The aim of the study was to assess the applicability of autoencoders for extracting features from the electromyographic signals and their spectral power with subsequent classification with an ensemble of decision trees using the random forest method. Experiments were carried out with data from two independent sets of electromyographic signals from two diagnostic groups: dysfunctional and functional pain. Signal preprocessing, autoencoder training with hyperparameter selection, performance comparison for different architectures and types of input data were performed. The results showed that features extracted directly from raw electromyographic signals have higher discriminatory power than features from spectral power. The best results were achieved for the stacked sparse autoencoders architecture with 5 autoencoders (7 features), achieving accuracy, F1-score, and AUC up to 1.00. The proposed approach demonstrates robustness to class imbalance and confirms the potential of autoencoder feature extraction with subsequent classification with an ensemble of decision trees for clinical diagnostics, especially when working with raw electromyographic data that preserves rich nonlinear dynamic characteristics of the signal.**

Keywords—class imbalance, electromyography, feature extraction, power spectral density, random forest, signal classification, stacked sparse autoencoder

I. Introduction

A wide range of features derived from electromyographic (EMG) signals have been proposed for the diagnosis of back pain. These features can be used to classify EMG signals recorded from individuals with various clinical conditions.

Both time-domain and frequency-domain characteristics of EMG signals have been investigated [1] – [4]. Time-domain features include statistical and correlation-based metrics, while frequency-domain features comprise spectral descriptors such as median frequency, mean frequency, peak frequency, mean spectral power, bandwidth, lower and upper frequency bounds, and average power within narrow frequency bands.

Additionally, nonlinear analysis techniques have been employed to extract diagnostic features from EMG signals. These include entropy measures [5], fractal dimension, parameters of the phase portrait [6], [7], second-order difference plots [8] and higher-order statistics [9].

Many of these features exhibit statistically significant differences between diagnostic groups, including patients with back pain of various etiologies and healthy controls. This suggests that they are informative and potentially valuable for diagnostic and classification purposes. However, identifying a single parameter or a combination of EMG-derived features that allows for reliable and unambiguous classification of back pain conditions remains an open and relevant research challenge.

II. Task

In this study, the objective was to investigate the applicability of the autoencoder method for extracting features from raw electromyographic signals, as well as from their frequency-domain representation in the form of power spectral density (PSD). These features were intended to serve as the basis for classifying the original signals into diagnostic groups. To achieve this, it was necessary to determine an optimal configuration of autoencoder parameters and to evaluate the possibility of using the extracted features for classifying EMG signals into two diagnostic categories—dysfunctional and functional back pain—using an ensemble classifier based on decision trees (random forest method).

III. Methods

A. Autoencoders

When dealing with complex data in machine learning applications, dimensionality reduction is commonly achieved by extracting informative features from the original dataset. Feature extraction techniques can be categorized into linear and nonlinear approaches, both of which transform the original data into a more compact, lower-dimensional form.

Linear approaches – such as factor analysis, linear discriminant analysis, and principal component analysis – convert the input into a new feature set by computing linear combinations of the original variables. These methods are straightforward and computationally efficient, particularly effective when the intrinsic relationships in the data are approximately linear. However, they tend to lose information when the data involve nonlinear dependencies or feature interactions.

Nonlinear approaches, on the other hand, project the data into a higher-dimensional feature space, enabling the identification of patterns that may not be visible in the original space. Among the most powerful tools for extracting complex features from nonlinear data is deep learning. Deep learning models are capable of automatically learning feature representations from raw input, thus minimizing the reliance on manual feature engineering.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

Various deep learning-based nonlinear feature extraction methods have been developed, including convolutional neural networks (CNN), recurrent neural networks (RNN), and autoencoders (AE). Models such as CNNs and RNNs generally require large volumes of labeled data for training, and the training process itself is often computationally demanding, necessitating high-performance computing resources [10].

AE are neural networks trained to reproduce their input at the output. They are mainly used for unsupervised learning tasks, i.e., they do not require labeled data during training.

An autoencoder consists of two main components – an encoder and a decoder (Fig. 1). The encoder and decoder may have multiple layers; in the simplest case, each of them has only one layer.

The encoder maps the input vector $x \in \mathbb{R}^{D_x}$ into a compressed representation (features) $z \in \mathbb{R}^{D^{(1)}}$ using the following transformation:

$$z = h^{(1)}\left(W^{(1)}x + b^{(1)}\right), \quad (1)$$

where the superscript (1) indicates the first layer;

$h^{(1)}$: $\mathbb{R}^{D_x} \to \mathbb{R}^{D^{(1)}}$ is the activation (transfer) function of the encoder;

$W^{(1)} \in \mathbb{R}^{D^{(1)} \times D_x}$ is the weight matrix;

$b^{(1)} \in \mathbb{R}^{D^{(1)}}$ is the bias vector.

The decoder, given an encoded representation of z, reconstructs an approximate copy of the input vector x as follows:

$$\hat{x} = h^{(2)}\left(W^{(2)}z + b^{(2)}\right), \quad (2)$$

where the superscript (2) indicates the second layer;

$h^{(2)}$: $\mathbb{R}^{D^{(1)}} \to \mathbb{R}^{D_x}$ is a transfer function for the decoder;

$W^{(2)} \in \mathbb{R}^{D_x \times D^{(1)}}$ is the weight matrix;

$b^{(2)} \in \mathbb{R}^{D_x}$ is the bias vector.

The network is trained to minimize a loss function that measures the difference between the original data x and the reconstructed data $\hat{x}$, for example in the form of the mean squared error.

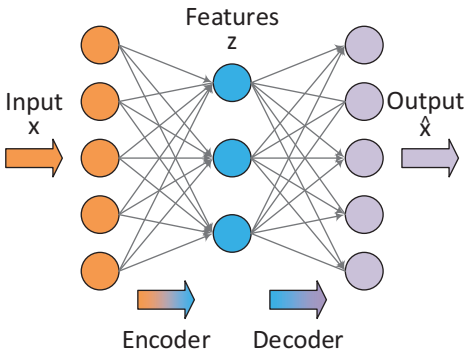

Fig. 1. Basic autoencoder diagram.

There are different AE architectures aimed at improving their efficiency for different tasks. Autoencoders that include different regularization methods are called regularized autoencoder (RAE).

A regularized autoencoder is a type of autoencoder in which additional constraints (regularization terms) on the model parameters or latent representation are introduced during training to improve the generalization ability of the network, avoid overfitting, and ensure that more informative and robust features are extracted.

Sparse autoencoders (SAE) use regularization techniques that force neurons in hidden layers to maintain a given level of sparseness, meaning that only a subset of neurons in the hidden layer are activated for an input example. This constraint forces the network to use individual hidden layer nodes for specific features of the input data, reducing redundancy in the input information.

The goal of sparse AE is to minimize the difference between the input and reconstructed data while adhering to the sparsity constraints of the hidden representation. The loss function of a sparse autoencoder consists of two components: reconstruction loss and sparsity loss.

Encouraging the sparsity of the autoencoder is possible by adding a regularizer to the loss function. This regularizer is a function of the average output activation value of the neuron. The average output activation measure of neuron i is defined as:

$$\hat{\rho}_i = \frac{1}{n}\sum_{j=1}^{n} z_i^{(1)}\left(x_j\right) = \frac{1}{n}\sum_{j=1}^{n} h\left(w_i^{(1)T}x_j + b_i^{(1)}\right), \quad (3)$$

where n is the total number of training examples;

x_j is the j-th training example;

$w_i^{(1)T}$ is the i-th row of the weight matrix $W^{(1)}$;

$b_i^{(1)}$ is the i-th input of the bias vector $b^{(1)}$.

A neuron is considered to be "activated" if its output activation value is high. A low output activation value indicates that the neuron in the hidden layer responds to only a small number of training examples. Adding a term to the loss function that constrains the values of $\hat{\rho}_i$ to be low encourages the autoencoder to learn a representation in which each hidden neuron is activated by only a limited number of training samples. In other words, each neuron becomes specialized, responding to a specific feature that is present only in a small subset of the training data.

The loss function minimized during training includes three terms:

$$E = \frac{1}{N}\sum_{n=1}^{N}\sum_{k=1}^{K}(x_{kn} - \hat{x}_{kn})^2 + \lambda\Omega_{weights} + \beta\Omega_{sparsity}, \quad (4)$$

where λ is the L_2 regularization coefficient;

β is the sparsity weighting coefficient.

The first term the loss function E is the mean squared reconstruction error (the difference between the input and the output), i.e., the network learns to reproduce the input. The second term is weight regularization, which helps prevent overfitting. The third term is a sparsity penalty (penalizing "overactive" neurons) to regularize the network's sparseness.

During the training of a sparse autoencoder, it is possible to reduce the sparsity regularization term by increasing the weight values $w^{(i)}$ and decreasing the values $z^{(1)}$. Adding a regularization term to the weights in the loss function prevents this behavior. This term is called the L_2 regularization term and is defined as:

$$\Omega_{weights} = \frac{1}{2}\sum_{l=1}^{L}\sum_{j=1}^{n_l}\sum_{i=1}^{k_l}\left(w_{ji}^{l}\right)^2, \quad (5)$$

where L is the number of hidden layers;
n_l is the output size of layer l;
k_l is the input size of layer l.

The regularization term L_2 is the sum of the squares of the elements of the weight matrices for each layer.

The sparsity regularizer imposes a constraint on the sparsity of the hidden layer's output. Sparsity can be encouraged by adding a regularization term that takes a large value when the average activation value $\hat{\rho}_i$ of neuron i deviates from its desired value ρ. One such sparsity regularization term is the Kullback-Leibler (KL) divergence, defined as:

$$\Omega_{sparsity} = \sum_{i=1}^{D^{(1)}} \mathrm{KL}(\rho\|\hat{\rho}_i) =$$

$$= \sum_{i=1}^{D^{(1)}} \left[\rho \log\left(\frac{\rho}{\hat{\rho}_i}\right) + (1-\rho)\log\left(\frac{1-\rho}{1-\hat{\rho}_i}\right)\right]. \quad (6)$$

The Kullback–Leibler divergence is a function used to measure how different two distributions are. In this case, it takes the value zero when ρ and $\hat{\rho}_i$ are equal, and increases as they diverge from each other. Minimizing the loss function forces this term to be small, which means that ρ and $\hat{\rho}_i$ must remain close to each other.

The results of the studies in [11] showed that the autoencoder significantly outperforms conventional machine learning models in the ability to detect anomalies in ECG data. However, the authors emphasize the sensitivity of autoencoders to the choice of hyperparameters and the need for large training datasets to achieve adequate performance. In [12], a stacked autoencoder was used to extract useful features from the surface electromyography signal to identify target finger movements from spectrogram and wavelet data, and in [13], the performance of stacked sparse autoencoders was evaluated to improve the myoelectric control of wearable prostheses based on surface and intramuscular electromyography records. The performance of stacked sparse AE showed better results compared to the linear discriminant analysis-based classifier. In [14], an EMG-based autoencoder method was tested for myocontrol. The performance of the autoencoder (AE) was compared with industrial state-of-the-art (SOA) control, and the results demonstrated that AE outperforms SOA. Results in [15] highlight the potential of AE to extract features from the power spectral density of pre-processed electroencephalography signals, which are subsequently classified by radial basis function neural network for early and accurate detection of Parkinson's disease.

Thus, the features extracted by SAE reduce the dimensionality of the data and can be used in combination with classifiers.

B. Random Forests

Random Forest (RF) is an ensemble classification method based on constructing a set of decision trees and combining their predictions to improve the accuracy and robustness of the model. The method was proposed by L. Breiman [16] and belongs to the family of bagging algorithms (bootstrap aggregating).

The main stages of classification by random forests include: the formation of training subsets, training of decision trees and voting (ensembling).

At the stage of formation of training subsets, N bootstrap samples are randomly generated (with replacement) from the original training set. The bootstrap method is a statistical technique in which multiple new subsets are randomly formed from the original training data with replacement. If the original training set contains N objects, then each bootstrap sample also contains N objects, but may include repeated elements, since each object is selected randomly and independently with the possibility of being selected more than once. This method is widely used in ensemble algorithms to improve robustness and reduce overfitting.

One decision tree is built for each bootstrap sample. During the tree training stage, each tree is trained on its corresponding bootstrap subset. This process introduces diversity among the trees. In the random forest method, the diversity between trees is further enhanced by applying feature subsampling at each node split, unlike standard decision trees, where all features are considered at each split to find the best one. Random forests consider only a randomly selected subset of features at each node and the best split is then determined from this subset. This technique reduces inter-tree correlation and increases the ensemble's robustness to overfitting.

At the final stage of classification, prediction is performed using majority voting. The majority voting process is a method of aggregating the decisions of multiple models (in an ensemble), in which the final prediction is determined based on the majority of votes from the individual models.

Let $\{h_1(x), h_2(x), \ldots, h_N(x)\}$ be the predictions of individual trees for the input vector x, then the final classifier is defined as:

$$H(x) = \mathrm{mode}(\{h_i(x)\}_{i=1}^{N}), \quad (7)$$

where $\mathrm{mode}(\cdot)$ is the function that returns the most frequent value (class).

The advantages of the random forest classifier are high robustness to overfitting, effectiveness on imbalanced datasets (with the use of class weights), and the ability to evaluate feature importance.

Majority voting makes the final decision more robust to errors of individual models by enabling mutual error compensation across the ensemble. Majority voting is a fundamental principle of ensemble learning, which is used in methods such as Random Forest, Bagging, and certain neural network ensembles.

In [17], the authors demonstrated the potential of using the random forest method for ECG signal classification to improve diagnostic accuracy. In [18], the random forest algorithm was used as a classifier for diagnosing cardiac arrhythmia based on statistical features extracted from the wavelet transform coefficients of ECG signals. The study showed that the RF classifier achieved better results compared to other methods. In [19], the reliable performance of the random forest algorithm was demonstrated for classifying patients with bipolar disorder and healthy individuals based on electroencephalogram data.

Thus, the random forest method was chosen as the classifier for the features extracted by the autoencoder.

IV. Experiments and Results

The original data for the study consisted of two sets of electromyographic signals recorded from the long extensor muscle of the trunk of the lumbar spine under the same conditions at different time periods. The EMG data were obtained in collaboration with the Department of Pathophysiology, Anesthesiology and Functional Diagnostics of the Sytenko Institute of Spine and Joint Pathology National Academy of Medical Sciences of Ukraine.

Each of the two data sets contains EMG signals of two diagnostic groups: 1 – conditionally healthy subjects with complaints of back pain, i.e., subjects without identified organic pathology (the so-called dysfunctional pain); 2 – subjects with back pain who have degenerative diseases of the spine (functional pain). In the first dataset, the number of signals was 46 (group 1) and 235 (group 2); in the second dataset, 38 (group 1) and 72 (group 2).

Pre-processing of the signals included filtering in the 10-500 Hz band and downsampling to 1024 Hz. The signals were cut to a 1-minute record length.

This study investigated the possibility of combining an autoencoder for extracting parameters from EMG signals with subsequent classification using the random forest method to determine group membership between two classes.

The signals from the first set were used to train the autoencoder and classifier. The obtained models were tested on the second data set.

A sparse autoencoder was chosen for the studies. As a result of the experiments, an optimal set of autoencoder hyperparameters was selected to obtain the best classification result. The studies were conducted both on the raw EMG signal and on its power spectral density (PSD), and in both cases the input signals were normalized. PSD was estimated using Welch's method. The original EMG signal was segmented into overlapping windows of length 256 samples, with 50% overlap (i.e., 128 samples). Each segment was multiplied by a Hamming window function, and the discrete Fourier transform was computed using a 512-point fast Fourier transform. Thus, the length of the autoencoder input vector is 61440 for the raw signal and 257 for the PSD. Different combinations of autoencoder parameters and its architecture were tested.

The logistic sigmoid function was used as the transfer function for the encoder and decoder.

The best results were achieved using the stacked autoencoder architecture (Fig. 2), consisting of five sequentially applied autoencoders, as shown in Fig. 2, and also with the addition of the sixth autoencoder, which reduces the number of features from 7 to 3. The stacked architecture implies sequential application of the autoencoders with a gradual reduction in the dimensionality of the feature space. The mean squared error was used as the training loss function with the addition of L_2-regularization with $\lambda = 0.001$, sparse constraint with the target average activation $\rho = 0.05$ (i.e., each hidden neuron should be active in about 5% of cases) and a sparsity coefficient $\beta = 4$ (the coefficient for the Kullback–Leibler divergence).

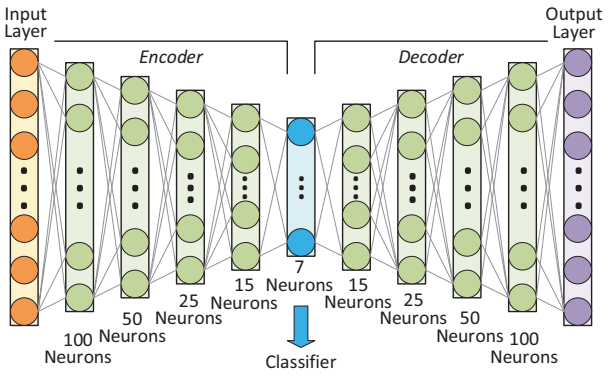

Fig. 2. Stacked autoencoder for feature extraction for subsequent classification.

An ensemble of 100 decision trees constructed using the random forest method was used as a classifier. Due to the significant class imbalance in the training dataset (46 samples in group 1 and 235 in group 2), class weighting was applied during classifier training to compensate for the imbalance. It was experimentally determined that the best classification performance was achieved with a class weight ratio of 3:1, assigning a higher weight to the minority class (group 1). This increases the sensitivity of the model to the less represented class, preventing it from being ignored during training.

The classification results on the test sample (accuracy, F1-score, AUC) are presented in Table 1.

TABLE I. Classification results using the random forest method for features extracted by the autoencoder

Input signal	AE Architecture	Accuracy	F1-score	AUC
Raw EMG signal	5 AE 7 features	1.00	1.00	1.00
	6 AE 3 features	0.97	0.96	1.00
PSD of EMG signal	5 AE 7 features	0.98	0.97	1.00
	6 AE 3 features	0.98	0.97	1.00

The results presented in Table 1 demonstrate the effectiveness of autoencoders (AE) for feature extraction from electromyography signals and subsequent classification with an ensemble classifier based on the Random Forest method.

When extracting features from PSD, classification based on 7 features obtained using a sequence of 5 autoencoders achieves high accuracy (0.98), F1-score is 0.97, and AUC is 1.00, which indicates high sensitivity and specificity of the model. A similar level of metrics is achieved when using a deeper architecture (6 autoencoders, 3 features), which indicates high information content of the extracted features, despite their small number.

It is noteworthy that the highest performance was achieved when raw EMG signals were used for feature extraction. The architecture with 5 autoencoders and 7 features produced perfect results. Even with strong compression down to 3 features (using 6 autoencoders), the model maintained high performance, confirming the robustness of the extracted features to dimensionality reduction.

Comparison of two types of input signals shows that features extracted directly from raw EMG signals have higher discriminatory power compared to features based on spectral representation (EMG PSD). High classification accuracy

achieved when using features extracted from raw EMG signals is probably due to the fact that the autoencoder receives significantly more information (61440 inputs) than in the case of spectral representation (257 inputs). Such high dimensionality allows the model to detect more complex and diverse patterns in the data, including temporal and nonlinear characteristics of the signal, which can be lost during preliminary spectral transformation. Using spectral-temporal representation of signals seems promising, since it can better reflect the nonlinear-dynamic nature of the EMG signal. At the same time, the main disadvantage of using raw signals is significantly higher computational costs at the stages of autoencoder training compared to processing spectral features. However, this factor does not affect the efficiency or speed of application of already trained models when they are used in classification problems, so it is rather an advantage, since it does not require pre-processing of data for their classification.

Thus, the presented results confirm the effectiveness of autoencoders to extract informative features from EMG signals and demonstrate the potential of using raw data to achieve high classification accuracy when powerful nonlinear dimensionality reduction methods are applied.

CONCLUSION

This study demonstrates the effectiveness of using stacked sparse autoencoders for extracting informative features from electromyographic (EMG) signals, followed by classification using a Random Forest ensemble. Both raw EMG signals and their power spectral density representations were evaluated as inputs to the autoencoder-based feature extractor.

The highest classification performance was achieved when features were extracted directly from raw EMG signals, with a compressed latent representation of only 3–7 features yielding accuracy, F1-score, and AUC values up to 1.00. Comparable, though slightly lower, performance was also observed when using spectral features. These findings suggest that raw EMG signals retain richer nonlinear-dynamic information beneficial for feature learning.

The results confirm that combining unsupervised feature extraction with ensemble learning provides a robust solution for EMG signal classification, even in the presence of class imbalance, and holds strong potential for diagnostic applications.

***Abstract* — This paper explores cybersecurity for Cardiovascular Monitoring Devices (CMDs) in IoT, addressing vulnerabilities in wireless networks like Wi-Fi and 5G. It compares traditional methods (AES-256, TLS 1.3) with post-quantum algorithms (CRYSTALS-Kyber, Niederreiter), emphasizing their quantum resistance. A hybrid approach using Quasi-Cyclic LDPC codes with Niederreiter is proposed to reduce key sizes, enhancing security and efficiency for CMDs against emerging quantum threats.Keywords— STM32, GD32, Glitch, Cold Boot Stepping, Electromagnetic Analysis .**

Keywords— Cardiovascular monitoring devices; cybersecurity; IoT; wearable technology; implantable devices; post-quantum cryptography; CRYSTALS-Kyber; Niederreiter; QC-LDPC; wireless communication; data protection; CMD security.

I. Introduction

Cardiovascular diseases (CVDs) are the leading cause of death globally, accounting for approximately 17.9 million deaths per year, or 31% of all global deaths, according to the World Health Organization. This growing burden is particularly pronounced among the aging population, which is projected to reach 17% of the world's total by 2050. In response, the development and deployment of Cardiovascular Monitoring Devices (CMDs)—both wearable and implantable—have become essential for continuous health monitoring and early disease detection.

Modern CMDs utilize technologies such as electrocardiographs (ECGs), implantable cardioverter-defibrillators (ICDs), and AI-integrated smartwatches to provide continuous health data. These devices are increasingly interconnected through IoT frameworks, cloud analytics platforms, and wireless communication protocols such as Bluetooth, Wi-Fi, ZigBee, and 5G. This connectivity enables real-time diagnostics and personalized treatment, yet also introduces serious cybersecurity risks.

Cyberattacks on CMDs, including data breaches and manipulation of device function, pose threats to patient safety, data privacy, and clinical reliability. Legacy encryption methods like AES-256 and TLS 1.3 are effective for many applications but may become obsolete with the rise of quantum computing. Post-quantum cryptographic algorithms, particularly CRYSTALS-Kyber and Niederreiter, offer enhanced protection but require optimization to meet the stringent energy and latency constraints of CMDs.

This paper provides a comprehensive review of CMD technologies, wireless protocols, cyber threats, and cryptographic defenses. It emphasizes the potential of integrating QC-LDPC codes into the Niederreiter cryptosystem to develop lightweight and quantum-resistant encryption solutions for future-proof cardiovascular health monitoring.

II. Main Research

Cardiovascular Monitoring Devices (CMDs) include implantable and wearable technologies such as electrocardiographs, implantable cardioverter defibrillators (ICDs), cardiac monitors, and smartwatches with heart rate monitoring capabilities. These devices provide continuous monitoring of cardiovascular activity, which is critical for early diagnosis and prevention of cardiovascular diseases (CVDs). According to the World Health Organization, CVDs cause 17.9 million deaths annually, accounting for 31% of all deaths worldwide [1], and the aging population (by 2050, the proportion of people aged 65+ will increase to 17% of the world's population [2]) is significantly contributing to the demand for CMDs. The elderly population is more likely to have CVDs, which requires continuous monitoring of heart rate and other parameters. Increasing awareness of CVD prevention among younger populations is driving the adoption of wearable devices that do not track heart rate or physical activity. Awareness campaigns supported by organizations such as the WHO and device manufacturers are helping to popularize CMD [1]. The global market for these devices is showing steady growth driven by technological innovation, increased health awareness, and economic factors.

Technological advances in CMD include the development of energy-efficient microprocessors, improved biosensors, and the introduction of wireless technologies for rapid data transmission. Implantable devices use minimally invasive technologies that reduce the risks of infections and

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

complications. Wearable devices integrate AI to analyze ECG data and predict abnormalities. Cloud platforms such as AWS HealthLake provide processing of large volumes of data, allowing doctors to obtain real-time analytics and tailor treatment to the patient's needs [3].

The global CMD market was valued at $28.5 billion in 2023 and is projected to reach $42.7 billion by 2030, at a compound annual growth rate (CAGR) of 6.9% [4]. The main drivers of growth are the demand for wearable devices, which accounted for 35% of the market in 2023 and are projected to grow to 48% by 2030 due to falling prices and widespread availability. Research and development (R&D) investments in medical technology annually account for approximately 10% of the total market, which is driving the emergence of new products with improved functions, such as biosensors with measurement accuracy of up to 95% [5].

TABLE I. KEY FINANCIAL INDICATORS OF THE CMD MARKET (2023–2030)

Indicator	Value 2023	Forecast 2030	CAGR, %	Main growth factor
Market size, $ bil.	28,5	42,7	6,9	Demand for wearable devices
Investments in R&D, $ bil.	2,85	4,27	7,0	Innovations in AI
Share of wearable devices, %	35	48	8,5	Price reduction
Share of implanted CMDs, %	40	36	5,2	Technological improvements
Marketing expenses, $ bil.	1,42	2,13	6,8	Awareness campaigns

Technological progress in CMDs is largely dependent on microprocessor architectures that provide data processing, energy efficiency, and integration with IoT. Modern CMDs use microprocessors with architectures such as ARM Cortex-M, RISC-V, MIPS, x86, and AVR, which optimize performance and power consumption. ARM Cortex-M is the leader in wearable devices due to its low power consumption (0.1–10 mW). RISC-V is gaining popularity due to its open architecture, which reduces licensing costs, and is suitable for implanted devices. MIPS and x86 are used in more complex stationary systems and cloud platforms, but have higher power requirements. AVR is used in simple wearable devices with low cost but limited performance [6].

TABLE II. COMPARISON OF MICROPROCESSOR ARCHITECTURES IN CMD

Architecture	Performance, MIPS	Power consumption, mW	Core size, nm	Application
ARM Cortex-M	100–1000	0,1–10	28–65	Wearable devices
RISC-V	50–800	0,2–15	22–65	Implantable devices
MIPS	200–1500	5–50	40–90	Stationary devices
x86	1000–5000	50–200	14–45	Cloud platforms
AVR	20–200	0,5–20	65–130	Simple wearable devices

Microprocessors enable ECG data processing, AI-based arrhythmia prediction, and wireless device integration. For example, the ARM Cortex-M in the Fitbit Versa enables energy-efficient sensor data processing, while x86 is used in cloud platforms for analyzing large amounts of data [7]. However, the use of IoT in CMD poses cybersecurity challenges, as each connected device is a potential point of vulnerability.

Wireless networks are the basis for data transmission in CMD devices. These technologies provide fast and convenient data exchange between devices and medical systems, allowing doctors to receive information about heart rhythm, electrocardiograms (ECGs), and other parameters in real time. However, their openness makes them vulnerable to cyberattacks, which threaten the confidentiality, integrity, and availability of data [8]. In the medical field, these threats are particularly dangerous, as they can lead to false diagnoses, device manipulation, or a threat to the patient's life.

Wireless technologies for CMD have different characteristics that affect their security. Wi-Fi (802.11ac) provides high bandwidth (up to 1300 Mbps), but high power consumption limits its use in implanted devices. Bluetooth LE (5.0) is energy efficient, but has a limited range (10–100 m) and weak encryption in older versions. ZigBee supports mesh networks with low power consumption, but speeds up to 250 Kbps are insufficient for large data. LTE and 5G offer high speed (up to 100 Mbps and 10 Gbps) and low latency, but depend on the operator infrastructure. LoRa provides a range of up to 15 km and ultra-low power consumption, but speeds up to 50 Kbps limit it for real-time monitoring [9].

The security level of the technologies varies: Wi-Fi with WPA3 is vulnerable to attacks on open networks, BLE 5.0 uses AES-128, but older versions are weaker. ZigBee supports AES-128 and mesh architecture, LTE and 5G use AES-256 and TLS 1.3, but are vulnerable to attacks on base stations. LoRa with AES-128 is suitable for low-frequency monitoring, but not for big data [5]. The choice of technology depends on the type of CMD, power requirements, and usage scenario.

Wireless networks used in CMD are subject to the following main types of attacks: data interception, man-in-the-middle (MITM) attacks, denial-of-service (DoS) attacks, firmware manipulation, and spoofing. Each attack has its own characteristics, potential consequences, and level of difficulty to implement. The level of security depends on the security measures applied, such as encryption, authentication, and network monitoring. Table 3 provides a comparison of the attacks and the corresponding security measures.

TABLE III. COMPARISON OF ATTACKS ON WIRELESS NETWORKS CMD AND SECURITY LEVEL

Attack type	Description	Potential consequences	Implementation complexity	Protection measures
Data interception	Obtaining data through weak encryption	ECG leak, medical history	Low	AES-256, TLS 1.3
Man in the Middle (MITM)	Interception and modification of communication	Incorrect commands, changing settings	Medium	WPA3, two-factor authentication
Denial of service	Network overload	Stop monitoring	Medium	IDS/IPS, traffic limiting
Firmware manipulation	Software change	Uncontrolled device operation	High	Digital signature, firmware update
Spoofing	Device identity spoofing	Data access, fake commands	Medium	Certificates, biometric authentication

Thus, analyzing the types of attacks, it can be noted that in Eavesdropping, attackers use weak encryption or insecure connections to obtain medical data. Vulnerabilities in Bluetooth connections allow interception of ECGs within a radius of up to 100 m, as was shown in 2019 [10]. Using AES-256 and TLS 1.3 significantly reduces the risk, but requires computational resources. In Man-in-the-Middle (MITM) attacks, the attacker intercepts the communication between the device and the server, modifying data or sending erroneous commands. For example, a MITM attack on a pacemaker can change the stimulation parameters, which is life-threatening. WPA3 and two-factor authentication reduce the risk, but vulnerabilities in Wi-Fi remain [11]. Denial-of-Service (DoS) attacks contribute to network congestion and block data transmission, stopping monitoring. For example, a DoS attack on a 5G network can delay the transmission of arrhythmia data. IDS/IPS systems and traffic throttling can help, but false positives can complicate the operation [12]. Firmware manipulation leads to changes in the CMD software. In 2011, researcher Barnaby Jack showed hacking insulin pumps via Bluetooth, which is relevant for CMD [13]. Using Spoofing, attackers forge the identity of the device, gaining access to data. Spoofing in a ZigBee network can imitate a legitimate device [14]. These attacks pose a serious threat to CMD, since a delay or error in data transmission can have fatal consequences. In 2023, 68% of cyberattacks in the healthcare sector were directed at IoT devices [14].

Based on this, it can be concluded that data protection in wireless networks for CMD faces several challenges.

– First, the limited computing resources of implanted devices make it difficult to use complex encryption algorithms (a pacemaker with a 5–10 year battery cannot support continuous AES-256 encryption without reducing its service life [15]).

– Second, the diversity of wireless technologies makes it difficult to standardize security protocols.

– Third, data transmission latency is critical for CMD: encryption can increase the latency in 5G networks (less than 1 ms), which is unacceptable for real-time monitoring [16].

– Fourth, vulnerabilities in firmware and outdated software remain a problem. Many CMDs do not support regular updates due to resource constraints.

– Fifth, the human factor plays a role: users may connect to unsecured networks or ignore updates, increasing the risk of attacks; 42% of data breaches in 2023 were caused by human error [17].

Wireless networks such as Wi-Fi, Bluetooth Low Energy, ZigBee, LTE, 5G, and LoRa, used in CMD, require data protection through encryption, authentication, and network monitoring. Modern methods ensure data confidentiality, integrity, and availability while minimizing power consumption and transmission latency, which is important for resource-constrained implanted devices [19]. Traditional methods such as AES-256 encryption, TLS 1.3 protocol, multi-factor authentication (MFA), and intrusion detection and prevention systems (IDS/IPS) remain relevant. However, post-quantum algorithms, such as CRYSTALS-Kyber (ML-KEM) and Niederreiter, are more modern and provide higher security for IoT, including CMD, due to their resistance to quantum attacks that threaten traditional methods [20]. AES-256 and TLS 1.3 are energy efficient, while IDS/IPS, CRYSTALS-Kyber, and Niederreiter require more resources, which may complicate their use in implanted devices. MFA increases security, but requires additional modules, which is a challenge for compact devices.

To evaluate the methods, performance indicators (probability of protection from attacks, %), implementation complexity (man-hours), power consumption (mW), processing latency (ms), and use cases were used. The power consumption of encryption algorithms is estimated using the corresponding formula 1:

$$E_{crypt} = N\left(E_{enec} + E_{dec}\right) \quad (1)$$

N_{crypt} – Number of encryption cycles;

E_{enec} – Energy for encryption of one block;

E_{dec} – Energy for decryption of one block.

The probability of successful protection against attacks depends on cryptographic strength, which can also be quantified, see Formula 2.

$$P_{\text{sec}} = 1 - \frac{1}{2^{k_{eff}}} \quad (2)$$

where: k_{eff} – the effective key length, taking into account resistance to quantum attacks;

Psec - protection probability (0 to 1).

TABLE IV. COMPARISON OF CYBERSECURITY METHODS FOR CMD WITH NIST COMPETITION RESULTS

Method	Efficiency, %	Implementation complexity, man-hours.	Power consumption, mW	Processing delay, ms	Example of use
AES-256	95	100	0.5	0.2	Data encryption in IoT
TLS 1.3	92	300	2.0	0.5	Data transmission in 5G
MFA	90	500	5.0	1.0	Access to servers
IDS/IPS	85	800	10.0	2.0	Network monitoring
CRYSTALS-Kyber (ML-KEM)	98	1200	15.0	3.0	Encryption in 6G/IoT
Falcon	96	1300	18.0	3.5	Encryption in IoT
HQC	97	1250	16.0	3.2	Backup encryption in IoT
McEliece	94	1400	20.0	4.0	Encryption in IoT (backup)
Niederreiter	95	1350	19.0	3.8	Encryption in IoT

The effective key length (bits), which takes into account resistance to quantum attacks.

Post-quantum algorithms such as CRYSTALS-Kyber, Falcon, HQC, McEliece, and Niederreiter are compared to traditional methods, demonstrating superiority in protecting IoT from quantum threats.

CRYSTALS-Kyber and HQC are distinguished by the highest efficiency due to their resistance to the quantum algorithms of Shor and Grover, providing reliable protection of the IoT against future threats [21]. Niederreiter, although less optimized, also outperforms traditional methods in terms of resistance (see Formula 2 in the formula file) [20]. The implementation of post-quantum algorithms requires significant effort, in particular for Niederreiter due to larger keys [11]. NIST (2024) tests on IoT devices show that CRYSTALS-Kyber is optimal in terms of power consumption and latency, while Niederreiter consumes more resources (see Formula 1 in the formula file) [25]. CRYSTALS-Kyber is standardized as the primary KEM (FIPS 203, 2024), Falcon and HQC are fallbacks, and McEliece and Niederreiter are alternatives for IoT [10, 22].

AES-256 is energy efficient (see Formula 1 in the formula file) and fast, making it suitable for implantable CMDs such as Medtronic pacemakers, due to its 0.2 ms real-time latency [23]. TLS 1.3 protects against MITM attacks and is effective for wearables such as Fitbit Versa, due to its low power consumption and 0.5 ms latency [24]. MFA is suitable for cloud platforms such as AWS HealthLake, but its power consumption limits its use in implantable CMDs [26]. IDS/IPS are effective for servers, but their power consumption and 2.0 ms latency create difficulties for devices [25].

CRYSTALS-Kyber, as a modern post-quantum algorithm, provides higher IoT security due to its resistance to quantum attacks, but its power consumption of 15.0 mW (see Formula 1 in the formula file) makes it difficult to use in implantable CMDs [24]. Falcon and HQC have similar characteristics but require significant resources [20, 24]. McEliece and Niederreiter outperform traditional methods in protecting IoT from quantum threats, but large keys and power consumption (19.0 mW for Niederreiter) limit their use in CMD (see Formula 3) [20, 23].

$$T_{\text{key}} = \frac{S_{key}}{R_{band}} \tag{3}$$

where: T_{key} – key transmission time (s).

S_{key} – key size (bits).

R_{band} – network bandwidth (bits/s).

CRYSTALS-Kyber is a leading post-quantum algorithm for IoT, including CMD. Its resistance to Shor and Grover quantum attacks makes it more advanced than AES-256, which could be cracked by quantum computers by 2030 [10]. Compact keys (800–1568 bytes) simplify exchange in 5G/6G networks compared to Niederreiter (100–500 kB) [23]. Latency of 3.0 ms is suitable for wearable IoT devices [24]. Compatibility with 6G networks (latency of 0.1 ms, speed of 1 Tbps) ensures relevance [25]. Support from IBM and Cloudflare increases trust after incidents, such as the St. Jude Medical incident in 2017 [19]. Power consumption of 15.0 mW makes it difficult to use in implanted CMDs [24].

Niederreiter, as a post-quantum algorithm, provides higher IoT security compared to traditional methods due to its resistance to quantum attacks [23]. Smaller keys than McEliece make it easier to use in IoT [24]. The simpler structure compared to Falcon facilitates implementation [19]. However, its power consumption of 19.0 mW and latency of 3.8 ms make it less efficient than Kyber [23].

A combination of methods is proposed to protect CMD. AES-256 is effective for current needs, CRYSTALS-Kyber for clouds and 6G networks due to its resistance to quantum attacks, Niederreiter is a fallback for IoT. 6G networks expected by 2030 will provide high speed and minimal latency, but will create new vulnerabilities [19]. Post-quantum algorithms such as CRYSTALS-Kyber and HQC will protect IoT from quantum computers, Niederreiter is an alternative if optimized [10]. Standardization by NIST and FDA will facilitate the implementation of post-quantum algorithms [20, 21].

CRYSTALS-Kyber is widely used in hybrid systems, where it is combined with classical KEMs like ECDH to protect IoT, including CMD. Its integration into AWS, Cloudflare, and IBM z16 demonstrates its practicality [23].

TABLE V. COMPARISON OF CRYSTALS-KYBER AND NIEDERREITER CHARACTERISTICS

Characteristic	CRYSTALS-Kyber	Niederreiter
Algorithm type	Key Encapsulation Mechanism (KEM)	Public-key encryption
The basis of security	LWE over the bars	Decoding linear codes
Efficiency, %	98	95
Standardization	NIST FIPS 203 (2024)	Not standardized
Public key, bytes	800–1568	~2 000 000 (128-bit security)
Secret key, byte	1632–3072	Smaller than the public key
Ciphertext, byte	768–1568	Depends on the parameters
Encryption speed	~10–20 us (IoT devices)	10 times faster than McEliece
Application	Key exchange, 5G/6G, IoT	Direct encryption, IoT
Prevalence	AWS, Cloudflare, IBM	Research projects

The Niederreiter cryptosystem, based on the decoding complexity of linear codes, uses large parity check matrices, which makes it difficult to implement in IoT devices such as CMD due to memory and computational resource limitations. The combination of the Niederreiter CCK with quasicyclic LDPC codes based on the circulant block structure allows for a compact representation of the matrices, reducing the size of the keys and increasing the decoding efficiency, which reduces the size and increases the efficiency of the CMD. This makes them promising for post-quantum security, where resistance to quantum attacks is key [19].

The combination involves the use of QC-LDPC codes as the base code in Niederreiter. The parity check matrix H is formed from circulant blocks, which reduces the memory requirements. Encryption is performed by calculating the syndrome, and decoding is performed using efficient algorithms such as belief. Security depends on hiding the code structure, making it difficult to decode without the private key [19].

Since QC-LDPC codes are a subclass of linear block codes with sparse parity check matrices consisting of circulant blocks. The circulant matrix is defined by the first row, where each subsequent row is its cyclic shift. For a vector[a, b, c] , the circulant matrix of size 3x3 has the form:

$$\begin{bmatrix} a & b & c \\ c & a & b \\ b & c & a \end{bmatrix}$$

This structure reduces memory requirements, as only the first line of each block needs to be stored, thanks to efficient decoding algorithms such as belief or minimum sum. Their flexibility allows tuning parameters such as code length n, dimensionality k, and error correction capability t to ensure security and performance [19].

The Niederreiter cryptosystem uses a parity check matrix H of size $(nk)\times n$ as the public key, and the private key includes a generator matrix G and a decoding algorithm. The encryption process consists of computing the syndrome $S= mHT$, where m is an error vector of weight t, representing the message. Decryption recovers s using a private decoding algorithm. Security depends on the complexity of decoding random codes without knowing the structure [10].

The combination of QC-LDPC codes from Niederreiter involves using QC-LDPC as the base code, which allows reducing the size of the keys and optimizing the calculations. The algorithm includes the following steps:

1. Code parameter selection: The parameters of the QC-LDPC code (n,k,t) are selected, where n is the code length, k is the dimension, and t is the number of errors to be corrected. For $n=1024, k=524, t=50$ the code provides 128-bit security [26]. The matrix H is formed as a block matrix of circulating blocks of size $m\times m$, where $m=n-k$.

$$H = [P_1 \times P_2 \ldots P_i] \quad (4)$$

where P_i are circulant matrices of size $m\times m$,

2 Key generation:

2.1 Private key: A QC-LDPC code is generated with a matrix H and a decoding algorithm (elief propagation).

2.2 Public key:

$$H_{pub} = S \times H \times P \quad (5)$$

Where: S – is a non-degenerate matrix;

P – is a permutation matrix that hides the structure of H.

The size of the public key for a QC-LDPC code is calculated as:

$$S_{key} = m \times l \times \log_2(\mathrm{q}) \quad (6)$$

Where: S_{key} – - key size (bits);

m – number of rows in the block $m=n-k$;

l – number of circulating blocks $l=n/m$;

g – field size $(g=)2$ for binary codes).

3 Encryption: Message m (error vector of weight $\leq t$) is encrypted as:

$$S = mH_{pub}^T \quad (7)$$

where S is the syndrome (ciphertext) $1\times(n-k)$;

H_{pub} – public key;

m – error vector of size $1\times n$;

H_{pub}^T – transpose matrix of H_{pub}.

4 Decryption: A private decoding algorithm is used to recover m from s, using a QC-LDPC decoding algorithm, such as elief propagation, with complexity $O(n\times d)$, where d is the density of the matrix H.

5 Optimization: FFT-based algorithms are used for calculations with circulant matrices, which reduces the complexity [25]. The probability of protection against attacks is estimated see Formula 2.

Thus, the implementation of the QC-LDPC combination algorithm with Niederreiter will allow to reduce the key size compared to traditional Hopp codes, which facilitates

transmission in low-bandwidth networks such as LoRa. For *n=1024, k=525, m=500*, the key size can be reduced to ~10–100 kB due to the circulant structure [25]. Efficient decoding algorithms, such as belief, reduce the computational complexity, which is critical for CMDs with memory up to 1 MB and power up to 1 MHz. Studies, such as in [19], show that QC-LDPC codes can be resistant to quantum Fourier sampling under certain conditions, such as uniqueness of elements in circulant blocks. However, some implementations have been found to be vulnerable to attacks, such as Sidelnikov-Shestakov, if the parameters are chosen incorrectly [19]. New schemes, such as the "tiny public key scheme", offer keys of 18–500 bits in size, but require security verification [25].

For CMD, combining QC-LDPC with Niederreiter [26] allows:

– To reduce key sizes, which facilitates transmission in 5G/6G networks.

– To provide quantum stability, which is critical for long-term protection of medical data.

– To use efficient decoding algorithms for fast message recovery.

Compared to CRYSTALS-Kyber [27] (keys 800–1568 bytes), Niederreiter with QC-LDPC can be faster in encryption, but requires optimization to reduce key sizes [22].

III. Conclusion

The combination of QC-LDPC codes with Niederreiter cryptosystem is promising for post-quantum IoT security, in particular CMD, due to the compact key representation and efficient decoding. The integration algorithm includes parameter selection, key generation, encryption and decryption using circulant matrices. The calculation formulas allow us to estimate the key size, stability and performance. However, careful security verification and optimization are required for practical implementation.

***Abstract*— The article considers the problem of using neural networks for predicting reactive power indicators in the power industry. It shows the relevance of the tasks of forecasting the consumption of electricity for planning the mode of operation of the enterprise, and establishes that the regulation of the level of reactive power allows to reduce electricity losses in grid elements and improve the quality of electricity. This work reviews and analyzes the works on reactive power compensation and determination of predictive values using artificial neural networks.**

Two options for forecasting the power factor and reactive power factor using artificial neural networks are considered. The first method is the direct forecasting of indicators, the second is the calculation of the components of indicators on the basis of predictive models on a schedule with accumulation. The period of the studied graphs is determined by the periodograms of the input data to justify the number of neurons in the input layer of neural networks. Predictive models based on a multilayer perceptron with linear, hyperbolic and exponential activation functions of neurons and the number of hidden neurons from 2 to 48 are presented.

The results of modeling by two forecasting methods are presented and the quality of the models on the accepted forecasting interval is compared in terms of network performance, the law of distribution of residuals and the root mean square error.

Keywords — neural network, forecasting, power factor, multi layer perceptron.

INTRODUCTION

Industrial processes have different needs for both active and reactive power. A significant aspect of energy saving in industrial enterprises is the compensation of reactive power – a component of the total power that characterizes electromagnetic processes in electrical networks. Excess of this component can lead to a significant increase in loss of active energy and voltage. To minimize losses, ensure stable operation of the network and increase its capacity, it is necessary to constantly optimize the level of reactive power in the network.

Due to the uneconomical transmission of reactive power to consumers, compensating devices are installed directly in the distribution networks of the enterprise to provide regulation of power in accordance with changes in loads in the network [1]. In this regard, there is a need to develop models that would forecast consumption volumes for the formation of regulatory influences.

I. ANALYSIS OF RECENT RESEARCH AND PUBLICATIONS

The relevance of the study is due to the need to influence the reactive power, which will improve the energy efficiency of existing power grids. When considering this issue, two components should be distinguished, each of which can be considered as a separate problem. The first is the technical implementation of reactive power control algorithms, the second is the formation of predictive control impact based on preliminary data on the operation of the enterprise.

The main task in planning the operation of reactive power sources is to provide the power system with sufficient reactive power under various conditions. Reactive power generation is used to maintain voltage levels and control the level of losses in the network. Under normal operating conditions, network losses can be reduced by proper reactive load control. Planning of the level of reactive power should take into account the operating time interval for each indicator in the planning horizon, which will ensure economic and safe operation [2].

Reducing power losses and improving power quality at the terminals of electrical receivers can be achieved by compensating for reactive power. A predefined cosφ can be used as an indicator of the optimal value of the level of reactive power consumption.. It is preferable to focus on those methods that are based on the study of forecast estimates that constitute the initial information for making management decisions to regulate the operation of compensating installations In this regard, it is advisable to

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

comprehensively regulate reactive power with a combination of voltage regimes in the system [3].

The work in the field of forecasting using artificial intelligence technologies is now gaining prominance in all areas due to the wide range of possibilities provided by artificial neural networks. Static forecasting models solve the tasks of detecting periodicity in data, analyzing dependencies, and assessing risks, among others. Promising forecasting methods are those based on artificial neural networks, which are able to comprehensively process information and identify hidden dependencies between input and output data [4-5].

Accurate forecasting of production process indicators is an important basis for ensuring the stable operation of the enterprise. Because some indicators, which are a complex nonlinear problem, are difficult to accurately reflect by existing forecasting methods, it is advisable to use an artificial neural network that can predict this indicator by a function infinitely close to any nonlinear function, which will be the most ideal forecasting method at the moment [6]. Artificial neural networks are widely used for forecasting as a powerful modeling method. Most neural network inputs for forecasting are single-factor, while certain process indicators can be multifactor. There are mixed results comparing the forecasting performance between neural networks and other models. The forecasting performance of neural networks can be improved by integration with other technologies. Nonlinear combination of forecasts using neural networks also gives encouraging results [7].

One of the most popular models of artificial neural networks is the Multi Layer Perceptron (MLP) network. On the basis of which it is possible to build accurate forecasts for grid operators when planning efficient generation schedules to meet the demand of electricity consumers. The artificial neural network model is an effective method for forecasts because it demonstrates such properties as the ability to adapt, the ability to learn from previous examples and the ability to generalize [8].

Among the unsolved problems remains the increase in the accuracy of forecasts of the level of reactive power as one of the factors influencing the quality of electricity at load nodes. To solve this problem, this work is being carried out, the scientific novelty of which lies in improving the quality of predictive models in energy through the use of artificial neural networks.

II. The Goal of This Paper

The paper investigates the indicators of reactive power consumed by the enterprise and neural network models that allow predicting their change. The aim of this paper is to construct a neural model of an enterprise that performs the functions of predicting the level of reactive power. To achieve this goal, the following tasks are solved in the work:

- Evaluation of indicators characterizing the consumption of reactive power by the enterprise and establishing their averaging intervals.
- Substantiation and configuration of an artificial neural network for forming a model of reactive power consumption by an enterprise.
- Forecasting reactive power consumption parameters and assessing the quality of the neuromodel.

III. Presentation of the Main Research Material

In practice, consumption or generation of reactive power is often characterized by the power factor cosφ or the reactive power factor tgφ. The value of tgφ from the point of view of mode analysis in conditions of high values of cosφ is considered to better reflect the impact of reactive power on processes [9]. The paper deals with the prediction of reactive power and power factors using artificial neural networks of the MLP type. The input data are represented by graphs of changes in active P=f(t) and reactive powers Q=f(t) (Fig. 1) and graphs of changes in power factor cosφ_i=f(t) and reactive power factor tgφ_i=f(t) (Fig. 2) (Numerical values of the samples used in the calculations are not given due to the significant amount of data). The samples cover a time interval of 10 days, which is 480 observations. Averaging of values was performed at an interval of 30 minutes (1 point of observation equal to 0,5 hour). The maximum value of active power is 400 kW, the maximum value of reactive power is 220 kVAr. Network training and forecasting will be performed based on 432 observations (9 days), and the data of the last day will be used as a test sequence.

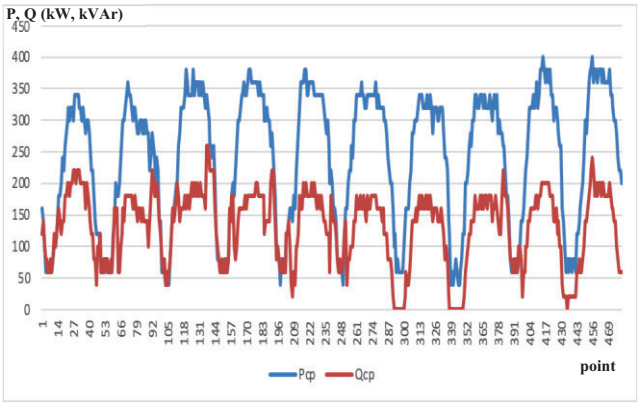

Fig. 1 Graph of changes in active and reactive capacities.

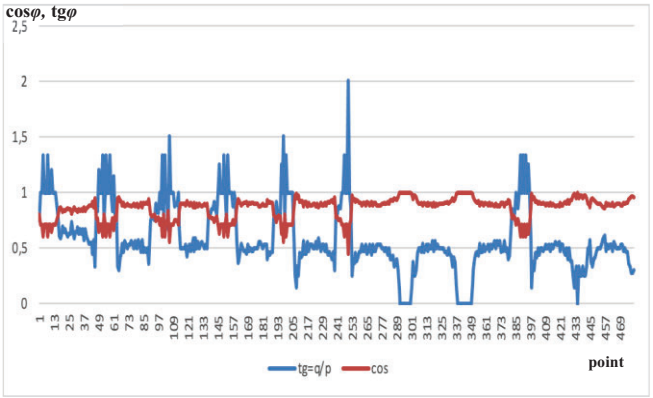

Fig. 2 Graph of changes in power factors and reactive power.

Modeling of neural networks is performed using the package "STATISTICA" [10].

The number of network neurons in the input layer is determined using the Fourier spectral analysis of the periodograms (Fig. 3-5). Fig. 3 shows the periodogram of the graph of reactive power change for the full range of the study, which determines the periodicity of the graph. In this case, the main period can be identified on the periodogram, which is 48 measurements, which corresponds to the number of measurements per day. The same regularities are observed

for the periodograms of power factor and reactive power factor. However, the presence of other peak values on the graphs indicates the possibility of changing the prediction period, and hence the number of neurons in the input layer.

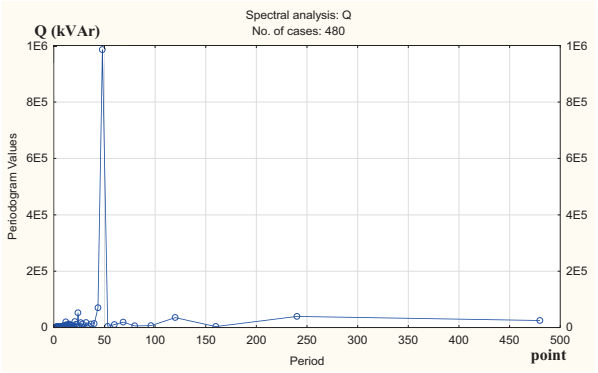

Fig. 3 Periodogram of the graph of reactive power change.

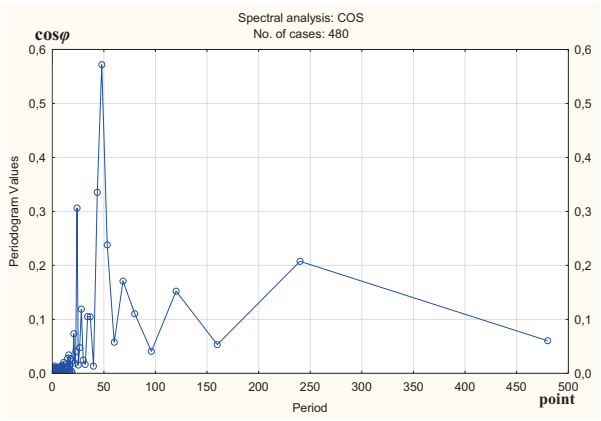

Fig. 4 Periodograms of graphs of power factor.

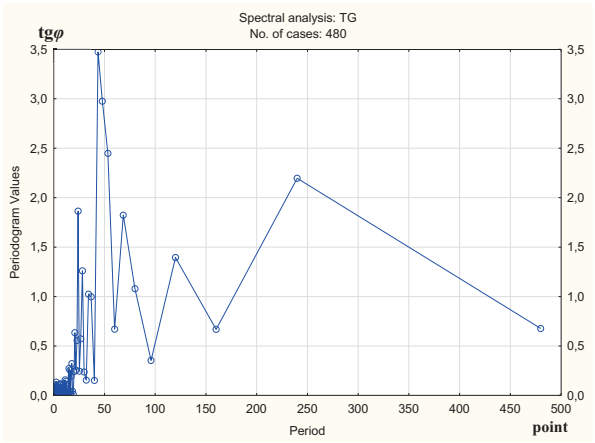

Fig. 5 Periodograms of graphs of reactive power factor.

Predicted values will be determined in two ways. According to the first one, the neural models of cosφ and tgφ will be built, and according to the second one, the forecasting of active and reactive powers will be performed and cosφ and tgφ will be calculated. Forecasting of capacities will be made on the basis of a graph with accumulation, since this method of forecasting avoids changing the sign of the derivative of the forecast function. The neuromodel uses a multilayer perceptron (MLP) that will be trained using the BFGS algorithm (Broyden - Fletcher - Goldfarb - Shanno algorithm).

The MLP structure involves 48 input neurons defined by periodograms, with one neuron in the output layer corresponding to the prediction task, and a variable number of neurons in the hidden layer from 2 to 48. Linear, hyperbolic, and exponential activation functions of neurons are used. The best configuration of the network will be determined by its performance. The quality of the models will be assessed by the performance (the correlation between the output and the predicted series), the distribution of residuals (the nature of the distribution of the differences between the input and the predicted values for all observations) and the average relative forecast error. Among the sample of 250 networks for each calculation option with randomly set initial conditions, 5 best ones were selected (Tables 1-2) for further analysis.

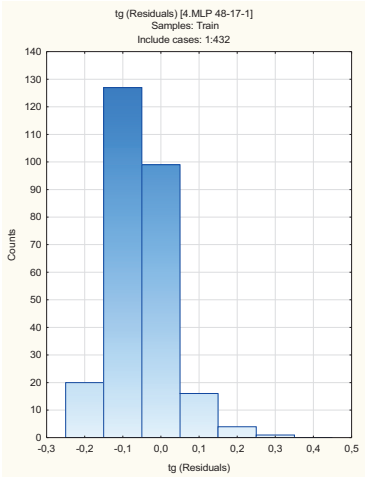
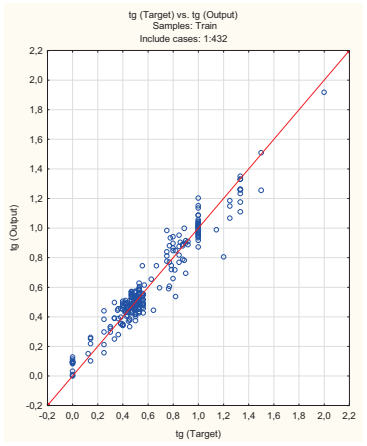
The constructed networks were analyzed by residuals distribution characteristics and a scatter diagram between input data and predicted values (Figures 6-7). The characteristics indicate a normal distribution of residuals, and the scatter diagrams indicate a trend towards a straight line, but do not completely coincide.



a)



b)

Fig. 6 Characteristics of the neural model for determining the power factor cosφ.

a)

b)

Fig. 7 Characteristics of the neural model for determining the power factor of reactive power tgφ.

For further evaluation of the obtained models, forecast charts for one day ahead were built for 48 forecast values (Figures 8-9).

Analysis of the results shows that, even with sufficiently high values of network performance (more than 95% on the test sequence and 89% on the test sequence), the forecast values for the daily interval have significant differences). The power factor schedule has significant discrepancies at the beginning of the forecast period, and the reactive power factor schedule does not show sufficient coincidence with the expected schedule. Therefore, direct forecasting for significant intervals without correction does not give sufficiently accurate results. Therefore, as an alternative forecast model, a forecast will be made on the basis of active and reactive power indicators obtained on the basis of schedules with accumulation. When constructing neural networks based on accumulation graphs for active and reactive powers, the values presented in Table 3 were obtained.

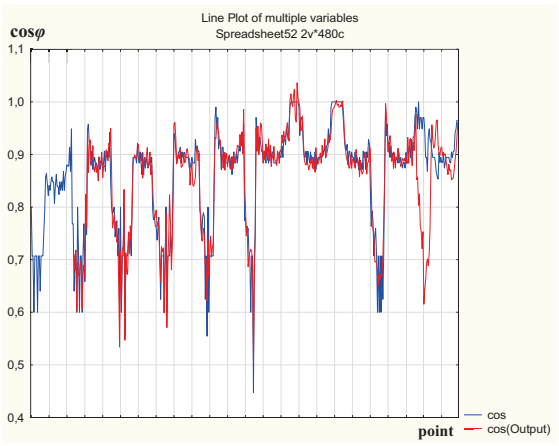


Fig. 8 Graphs of changes in the power factor cosφ for input data and neural model with a forecast for 1 day.

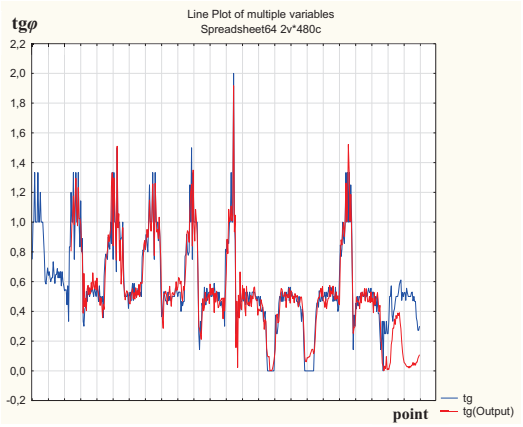

Fig. 9 Graphs of changes in the power factor cosφ for input data and neural model with a forecast for 1 day.

The obtained networks are characterized by high performance (over 97.5% on the test sequence and over 98.5% on the control sequence) and have a normal distribution of residuals. Based on the MLP 48-39-1 and MLP 48-12-1 networks, the values of cosφ and tgφ are calculated. Since the networks built a graph with accumulation, to determine the indicators, the values were recalculated into a number of absolute values of capacities.

$$P_i' = |P_{i+1} - P_i| \quad (1)$$

$$Q_i' = |Q_{i+1} - Q_i| \quad (2)$$

where P_i' , Q_i' - are absolute values of consumed active and reactive powers; P_i, Q_i - are modeled according to the schedule with accumulation of active and reactive power values.

The results of forecasts obtained by the proposed models are presented in the graphs (Fig. 10-11). Compared to the previous models, the graphs show better agreement with the test sequence. The average relative error for the predicted cosφ plot (Fig. 10) is 5,3 %, and for the tgφ plot it exceeds 10 %. The tgφ plot has significant excesses of the predicted peak values, which leads to a decrease in the overall accuracy of the model. Consequently, when forecasting reactive loads, it is advisable to use a combination of direct forecasts of reactive power consumption and calculated values of cosφ obtained from graphs with accumulation (readings of power meters).

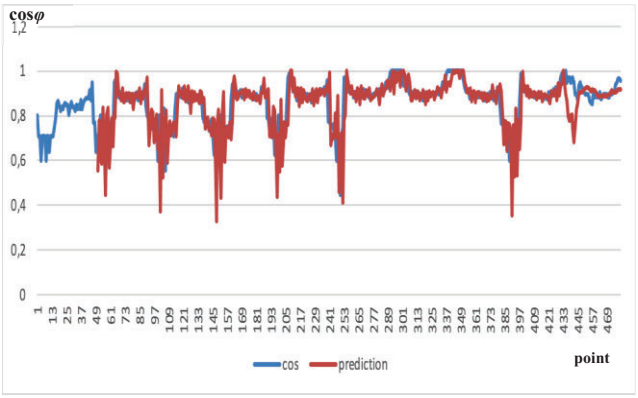

Fig. 10 Input graph cosφ against the prediction.

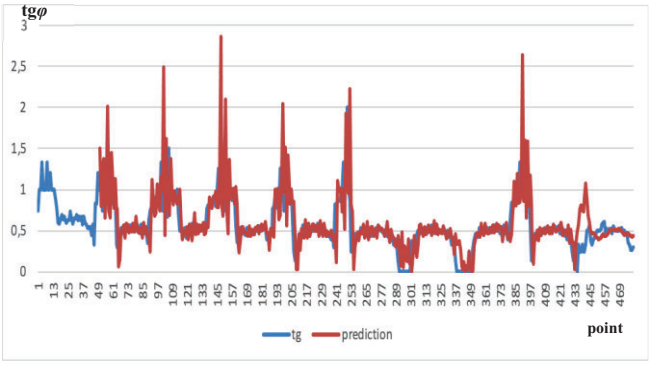

Fig. 11 Input graph tgφ against the prediction.

CONCLUSIONS

The use of artificial neural networks for building models for predicting reactive load indicators is substantiated.

The required number of neurons (48) in the input layer is determined by half-hourly graphs of active and reactive loads and their indicators. Reducing the number of neurons will worsen the quality of the model due to a period mismatch and increasing it will increase the computation time.

Given that the average relative error for the predicted cosφ graph is 5,3 %, and for the tgφ graph it exceeds 10 %, it is advisable to use the predicted values of active and reactive power meters and the calculated cosφ value to determine the required level of reactive power compensation.

The obtained values allow the use of neural network models based on a multilayer perceptron that predicts the value of cosφ for building systems for automatic power control of compensating devices with a variable load schedule.

Abstract. **The article presents research on the prospects of using the relative dielectric permittivity (ε^t) of crude oil as a process parameter during its refining. It has been established that ε^t demonstrates a strong correlation with kinematic viscosity and Conradson carbon residue. Based on the conducted studies, a predictive criterion (PC) has been proposed, which enables the identification of rational oil refining schemes aimed at increasing the yield of valuable products and reducing production costs.**

Keywords: crude oil; refining; dielectric permittivity; processing scheme; resins; asphaltenes; viscosity; Conradson carbon residue; density

I. INTRODUCTION

Nowadays, oil refining is considered one of the strategic industrial sectors of Ukraine, and the economic situation of the country significantly depends on its development. This industry produces a variety of petroleum products, including gasoline, diesel fuel, fuel oil, lubricants, and road and construction bitumen, all of which are in high demand.

Recently, Ukraine's oil refining sector has been facing a number of challenges:

- a reduction in processing volumes due to the shutdown of production processes at most refineries caused by equipment wear and tear, low technological level of processing units, and insufficient investment;
- a significant dependence on imported petroleum products, affecting the country's energy security;
- the impact of military actions, which have caused major infrastructure destruction and the suspension of operations at most refineries.

At the same time, the development prospects of Ukraine's oil refining sector can be outlined in the form of a structural scheme shown in Figure 1.

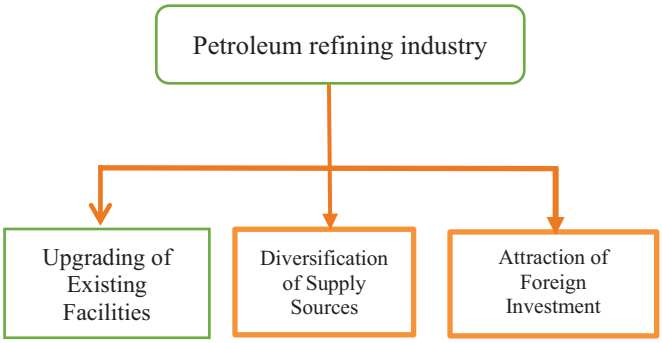

Fig. 1. Prospects for the development of the oil refining industry in Ukraine

II. Purpose and Research Objectives

In our view, the modernization of existing capacities represents a key strategic direction for the development of Ukraine's oil refining industry, one that depends entirely on the domestic scientific potential and can be implemented in the short term. The main aspects of such modernization include the improvement of technological processes through the use of new construction materials, catalysts, and engineering solutions, as well as continuous monitoring of the technological process. It is the process monitoring that has been selected as the primary focus of modernization for the current oil refining capacities in Ukraine's industrial sector. To implement this monitoring, we have employed the parameter of relative dielectric permittivity (ε^t) of crude oil – the primary hydrocarbon feedstock used in the production of commercial petroleum products. The parameter (ε^t) characterizes the insulating properties of the medium – in this case, crude oil – which may vary under the influence of numerous factors such as chemical and fractional composition, and the presence of contaminating impurities. In both oil production and refining industries, the ε^t parameter holds practical significance and is widely applied across several key directions (presented on the Fig.2)

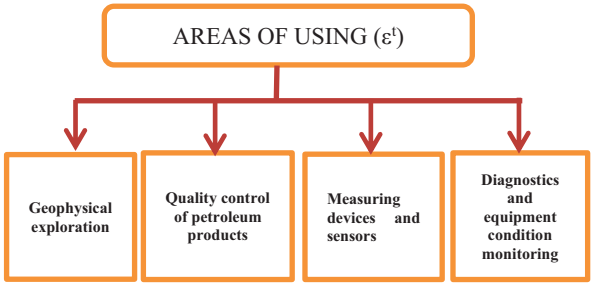

Fig. 2. Key applications of the parameter (ε^t) in the petroleum extraction and refining industries

Geophysical exploration for oil and gas deposits employs electrical prospecting methods, in particular dielectric probing techniques [4, 5]. Due to the significant difference in dielectric permittivity between formation water (~80 units) and crude oil (~2–4 units), this contrast is utilized for identifying oil-bearing strata. Geophysical exploration also incorporates radar-based investigation techniques, such as Ground-Penetrating Radar (GPR) [6]. In these applications, radio wave propagation is influenced by the stratigraphic profile, and the ε^t parameter directly affects the speed and reflection of waves [7].

Quality control of petroleum products.

The dielectric permittivity (ε) of crude oil is indeed an integral parameter and is highly dependent on its composition. Typically, an average experimental value is used; however, if it is necessary to account for the influence of individual components, a mixing approach is applied (construction of calibration curves) considering their polarity. In practice, it is sufficient to determine the dielectric permittivity value of crude oil within the range of critical thresholds, which indicate the presence of contaminating impurities in the oil.

Measurement of ε^t is applied to identify the composition of liquid hydrocarbons and detect the presence of water or other polar impurities [8, 9]. For instance, in [10], an index of oil preparation (IOP) is proposed, which is a function of the dielectric permittivity parameter ε^t.

Measuring devices and sensors. Sensors based on the principle of ε^t measurement are used in tanks and pipelines to determine crude oil levels [11], detect phase boundaries (oil–water), and monitor the formation and breakdown of emulsions such as "water-in-oil" or "oil-in-water" [12, 13].

Diagnostics and equipment condition monitoring. In dielectric testing of insulation materials, hydraulic fluids [14], and transformer oils [15, 16], the ε^t parameter is also considered. This enables the detection of material degradation, presence of water or impurities, which are undesirable and may lead to failure during operation of electrical equipment.

Crude oil and its refined products belong to nonpolar liquids. For such systems, a decrease in ε of approximately 0.2–0.5% per each 1 °C increase in temperature is typical. This can be explained by the reduction in density upon heating: the molecules move further apart, and their polarizability per unit volume decreases. Therefore, all dielectric permittivity measurements were carried out at a fixed temperature.

Since ε^t is a critical physical property widely used in oil extraction and refining, we propose an alternative application: using ε^t for real-time monitoring of the crude oil refining process. Specifically, this involves assessing the degree of distillate fraction recovery relative to their potential content in crude oil. The ε^t parameter correlates with the depth of crude oil conversion and directly impacts the operational efficiency of primary refining units.

The dielectric permittivity (ε) is one of the most sensitive parameters to moisture and emulsification in crude oil and petroleum products. Considering that dehydrated crude oil has $\varepsilon \approx 2–2.5$, while water has $\varepsilon \approx 80$, even trace amounts of water (0.1–0.5%) in oil significantly increase its effective ε. The corresponding relationship is quadratic polynomial in nature. Moreover, the higher the moisture content, the faster ε increases, especially during the transition from water microdroplets to macro-droplets. When a stable emulsion is formed, the dielectric permittivity of the mixture can be described by effective medium models (e.g., the Maxwell–Garnett or Bruggeman formulas). The smaller and more uniformly dispersed the water droplets, the closer the ε of the emulsion approaches the average value between that of oil and water. For “oil-in-water” type emulsions (rare in petroleum refining), ε is even higher, since the nonpolar phase acts as the dispersed medium.

The primary instruments for obtaining real-time information on material flows are capacitive sensors, which transmit data to the DCS (Distributed Control System). Key installation points for these sensors include: the crude reception unit (online monitoring of water-in-oil content and batch stability); upstream and downstream of the electro-dehydrator (control of voltage, demulsifier dosing, and recirculation); on return/discharge lines of emulsions (signaling phase separation and water carryover); and in tank farms (recirculation loop) for long-term monitoring of the water/sludge balance.

In addition, it should be mentioned that based on common practice at refineries and chemical plants, it should be noted that scheduled calibration of capacitive sensors is carried out once every 6–12 months (in accordance with the manufacturer’s specifications and the internal regulations of the metrology service). Unscheduled calibration is performed after repair or replacement of cables/electronics, after process reconfiguration, or in case of sharp deviations in readings (instability, “floating” values). In critical systems (such as tank level monitoring of petroleum products and online water content measurement in crude oil), calibration may be required quarterly or even on a monthly basis. If the sensor operates under relatively stable conditions (constant temperature, absence of deposits), annual calibration is sufficient. In environments with a high risk of deposit or emulsion formation, accuracy verification is typically performed every 3–6 months.

Standardization of the proposed methodology, however, may be complicated by several factors: variability of crude oils from different fields, influence of moisture and emulsions, temperature dependence, differences in

instrumentation and calibration procedures, as well as the absence of unified international standards. Nevertheless, the most promising approach involves developing correlation models in which dielectric permittivity (ε) is integrated with other parameters (density, viscosity, resin and asphaltene content) within a unified methodology.

III. RESULTS AND DISCUSSION

When analyzing the dielectric permittivity parameter of crude oil (ε_{oil}) and gas condensate ($\varepsilon_{g.c.}$) feedstocks, the following relationship can be observed:

$$\varepsilon_{g.c.} < \varepsilon_{oil.} \quad (1)$$

This relationship is determined by the fractional composition of gas condensates: the content of light fractions that boil at temperatures up to 360 °C constitutes 80–95 vol.%, whereas in crude oil such fractions do not exceed 60 vol.%. Additionally, gas condensates contain lower amounts of sulfur compounds, resins, and asphaltenes compared to crude oil feedstock [17].

Therefore, we propose a predictive criterion (PC) for determining the processing direction of petroleum feedstock, which in general form can be expressed as:

$$PC = A_1 \times X_1 + A_2 \times X_2 + A_3 \times X_3 + \cdots + A_n \times X_n \quad (2)$$

where A_1–A_3 are dimensionless weighting coefficients of the quality indicators,

X_1 to X_n are the quality parameters of the petroleum feedstock.

The proposed criterion is based on the interrelation between the dielectric permittivity ε^t and other quality indicators of the feedstock. This is due to the fact that crude oils from different fields can significantly differ in their group chemical composition, which makes it impossible to obtain adequate information about them relying solely on the ε^t parameter values.

The practical application of equation (2) involves the use of physicochemical quality indicators of the crude oil feedstock. Among the most informative quality indicators that can be used in equation (2) are kinematic viscosity and Conradson carbon residue.

Kinematic viscosity (ν, mm²/s) is one of the most important technological properties of crude oil, which depends on its fractional and chemical composition (the higher the content of high-boiling fractions in the feedstock, the higher its viscosity) and characterizes the pumpability of oil during its transportation through refinery pipelines. Additionally, kinematic viscosity allows assessing the suitability of crude oil for the production of lubricating materials. That is, hydrocarbon feedstock with a high kinematic viscosity value ($\nu^{20} \geq 150$ mm²/s) is advisable to be used for manufacturing various types of liquid lubricating oils. Based on literature data [18], related to the use of kinematic viscosity in various technological calculations, the value of viscosity measured at 20 °C or 40 °C should be used in equation (2).

The choice of Conradson carbon residue (X_c, wt.%) for characterizing crude oil is explained by the fact that its value strongly depends on the content of resins and asphaltenes (ha) in the feedstock. When their content is high ($h_a \geq 20$ wt.%), typical for heavy crude oil, the production of high-quality base oils—the main component for manufacturing commercial lubricating oils—becomes complicated. This necessitates the use of special (selective and adsorption) methods for deep purification of the obtained base oils.

Moreover, kinematic viscosity and Conradson carbon residue exhibit a close correlation with the ε^t parameter, as confirmed by our experimental studies and illustrated in Figures 3–4. It is evident that with an increase in the content of high-molecular-weight hydrocarbons (resin-asphaltene substances) in the oil, which have boiling points above 350 °C and contain molecules of O, S, N, and metals (V, Ni), the value of the ε^t parameter increases. This, in turn, is fully consistent with existing understanding of the contributions of various factors to the ε^t parameter magnitude.

Based on the information presented above, the model for determining (PC) will take the final form as follows:

$$PC = A_1 \times \varepsilon + A_2 \times \nu^t + A_3 \times X_c \quad (3)$$

where ν^t is the kinematic viscosity of the crude oil at 20 °C or 40 °C, mm²/s; X_c is the Conradson carbon residue of the crude oil, wt.%.

Currently, the main processing options for crude oil implemented at petroleum refining enterprises include fuel, lubricating oil, and combined processing [19].

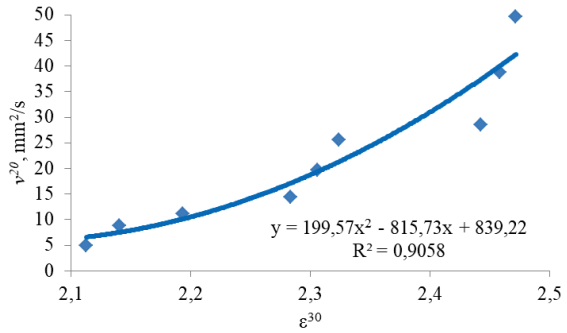

Fig. 3. Effect of the parameter ε^{30} on the ν^{20}

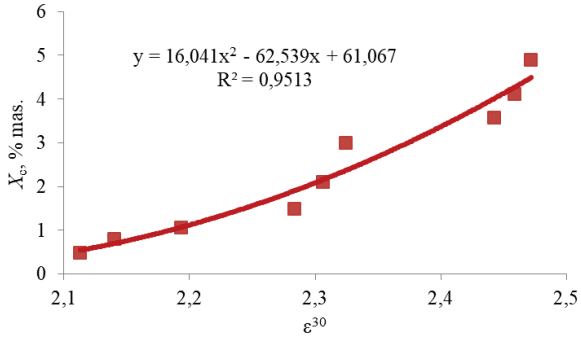

Fig. 4. Effect of the parameter ε^{30} on X_c

Based on these standard processing routes, Figure 5 graphically presents the main existing options for crude oil processing depending on the value of PC (RPC). According to Figure 5, for each crude oil processing route, the following expressions can be obtained:

$$P_{PC}^{F} < P_{PC1} \quad (4)$$

$$P_{PC1} \le P_{PC}^{F} \le P_{PC2} \quad (5)$$

$$P_{PC2} \le P_{PC}^{F} \le P_{PC3} \quad (6)$$

where P_{PC}^{F} is the actually determined level of PC; P_{PC1}, P_{PC2}, P_{PC3} are the experimentally established boundary values of PC for each crude oil processing option.

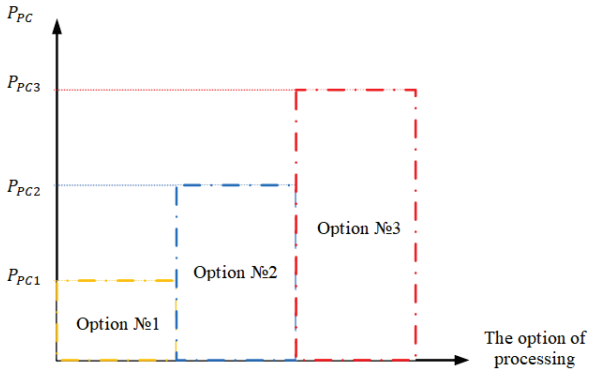

Fig. 5. Directions of refining at different P_{PC}

It should be noted that a physicochemical quality indicator of crude oil such as density (ρ^{20}, kg/m³), which reflects its chemical composition and serves as the basis for its classification [20], according to which rational processing options must be developed, has a rather close correlation with the parameter ε^{30} (see Fig. 6).

It is clear that light crude oils are characterized by a higher content of light fractions, which mostly consist of alkanes and naphthenes, and a lower content of aromatic hydrocarbons. Heavy crude oils mainly consist of high-boiling fractions (boiling point above 350 °C), which contain a significant amount (on average up to 8%, and sometimes up to 20%) of resinous-asphaltene substances. Such a distribution of hydrocarbons in crude oils also affects the magnitude of the ε^{30} parameter.

Then, expression (4) is characteristic of light crude oil (density from 830 kg/m³ to 850 kg/m³) and gas condensate with a high (35–95%) content of fuel fractions boiling up to 350 °C. For processing such feedstock, the use of "Option No. 1," based on primary processing, is economically feasible. The main products of this processing route are motor fuels and boiler fuels.

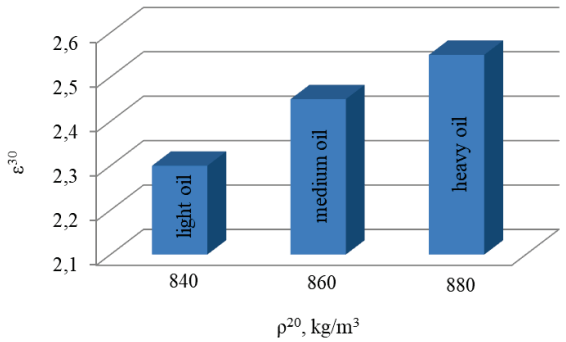

Fig. 6. Average value of ε^{30} depending on the average value of ρ_{20} for each crude oil group

Expression (5) is characteristic of medium crude oil (density from 850 kg/m³ to 870 kg/m³) with an average (up to 20–35%) content of fuel fractions boiling below 350 °C.. For processing such feedstock, "Option No. 2," which includes combined use of primary processing with subsequent dewaxing and deasphalting of the obtained lubricating fractions or the use of hydrocracking of heavy oil fractions, is economically feasible. The main products of this processing route are purified base oils for the production of industrial, high-viscosity-index (with viscosity index above 130 units) motor oils, as well as transmission oils. By-products include motor and boiler fuels.

Expression (6) is characteristic of heavy crude oils (density above 870 kg/m³) with an average (up to 20%) content of fuel fractions boiling up to 350 °C. For processing such feedstock, "Option No. 3," which involves combined use of primary processing with subsequent hydrocracking, visbreaking, or coking of high-boiling fractions and residues, is economically feasible. The main products of this route are motor, process, and boiler fuels. When implementing this option, additional use of the heavy residue oxidation technology can be proposed to produce road and construction petroleum bitumens [21], which in this case can be considered as by-products of the production.

Considering all of the above, it should be noted that the industrial implementation of the procedure for the rapid determination of the rational crude oil processing option depending on the value of its parameter (ε^{t}) is one of the strategically important stages that allow optimizing feedstock (crude oil) utilization, increasing the yield of valuable products, and reducing costs in the petroleum refining industry.

IV. CONCLUSIONS

The conducted theoretical studies have shown that the parameter of the relative dielectric permittivity of crude oil, ε^{t}, can be used during the technological processing of crude oil, particularly for determining the processing scheme option.

It has been experimentally proven that there is a close correlation between the parameter ε^{t}, kinematic viscosity (ν^{20}, mm²/s), and Conradson carbon residue (X_c, wt.%), which is manifested by an increase in the ε^{t} value with increasing ν_{20} and X_c of the crude oil.

A predictive criterion (PC) for the direction of crude oil processing has been developed, which includes the determination of the ε^{t} parameter along with additional quality indicators such as kinematic viscosity and Conradson carbon residue. The practical application of the PC involves the experimental determination of certain threshold levels and allows for the formulation of rational technological crude oil processing schemes considering its electrophysical properties expressed by the ε^{t} parameter.

These schemes, depending on the value of the predictive criterion (PC), can be classified into fuel, lubricating oil, and combined processing options. Depending on the demand for specific petroleum products, the target components obtained by implementing these schemes include hydrocarbon gases, motor and boiler fuels, lubricating oils, petroleum coke,

bitumens, and by-products such as destruction gases, paraffin, resins, and asphaltenes.

***Abstract*— This paper explores the use of surface coatings on decelerating structures to enhance the power output of millimeter and submillimeter wave generators. By applying metallic and dielectric coatings, we investigate their effects on electron beam dynamics and power conversion efficiency. Experimental results show that surface coatings reduce energy losses and improve electron-beam interactions, leading to significant increases in system efficiency. The study highlights the role of coating properties such as conductivity and thermal management in optimizing performance. These findings provide insights into improving the efficiency and power of high-frequency wave generators, with potential for further advancements through novel materials and design approaches.**

Keywords— backward wave tube (BWT), diffraction radiation generator (DRG), electron beam, slow-wave structure, terahertz radiation.

I. Introduction

Backward wave tubes (BWTs) and diffraction radiation generators (DRGs) are crucial for microwave and millimeter-wave applications in radar, telecommunications, and spectroscopy [1]–[3]. These devices use an electron-optical system with a slow-wave structure (SWS) to enable frequency tuning and power extraction. However, power conversion efficiency remains a challenge, especially at terahertz (THz) frequencies.

BWTs offer broad electronic tunability but typically operate at low power levels in the millimeter-wave range [4]. Efficiency is hindered by the exponential attenuation of the first negative spatial harmonic of the electromagnetic wave (EMW) and the non-uniform electron beam (EB) interaction across its thickness [5], [6]. Only the EB layers near the SWS surface experience strong field interaction, while charge-depleted regions, beam pulsations, and weak impedance coupling further limit power conversion, particularly in the THz range [7], [8]. Additionally, shorter wavelengths impose strict constraints on EB thickness and demand higher current densities, pushing the technological limits of BWTs [9].

DRGs face similar challenges, where space-charge effects and non-uniform field distributions further impede EB interaction and power extraction [7]. Addressing these issues through advanced materials and refined electron-optical designs can enhance high-frequency wave generation. This study explores surface coatings on SWS to improve BWT/DRG efficiency. By analyzing metallic and dielectric coatings, we assess their impact on EB dynamics and power conversion.

The paper is structured as follows: Section II discusses challenges in conventional BWT/DRG and possible solutions; Section III examines EB dynamics in BWT/DRG with a dielectric-coated SWS; Section IV explores periodic SWS construction of the braking electric field for BWTs/DRGs using dielectric coatings; and Section V and Section VI presents the discussion and conclusion, respectively.

II. Challenges in Conventional BWT/DRG and Possible Solutions

A. Development of BWTs and DRGs

To overcome these limitations, optical BWTs known as "Clinotrons" were developed [1], [2] (Fig. 1). In a Clinotron, a ribbon-shaped EB strikes the periodic SWS (comb) at an acute angle, enhancing interaction with the high-frequency field and boosting power generation by engaging all EB layers. A similar inclined injection method was applied to DRGs, significantly increasing output power in the millimeter and submillimeter ranges [3], [6] (Fig. 2) compared to conventional axial EB injection, due to improved energy utilization.

This enhanced power generation in DRGs is attributed to the inclined injection geometry, where the sheet EB impinges on the periodic SWS—such as a comb—at an acute angle φ_0. This ensures that different EB layers sequentially enter the high-intensity electromagnetic field, allowing all electrons in the sheet beam to interact effectively with the high-intensity electromagnetic field on the comb surface, thereby improving energy transfer efficiency.

Schematic diagram of the classical clinotron: (1) vacuum chamber, electron-optical system (2) that forms the paraxial sheet EB (3), periodic SWS (4), where the interaction surface is positioned at an acute angle to the axis of the paraxial strip EB (3), with a thickness equal to or greater than λ, where λ is the average wavelength of the slowed wave across the working range, and the output waveguide (5).

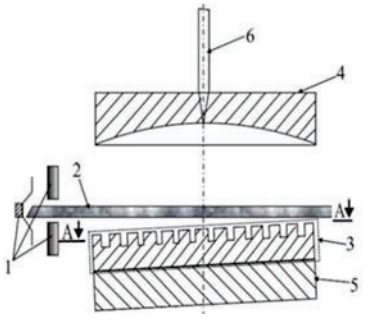

Fig. 2. Schematic diagram of the DRG: (1) electro-optical system ,which emits the electron flow and shapes it into a paraxial sheet EB (2); periodic SWS interaction surface (3), positioned at an acute angle to the EB; and mirror (5), which supports the periodic SWS.

B. Experimental Observations & Design Limitations

Experimental results [6] indicate that, as the wavelength λ decreases in DRGs and Clinotrons, the starting current increases, the initial value of the focusing magnetostatic field rises, and the generator's output power significantly decreases at λ = 0.8 mm. These effects are attributed to increased ohmic losses in the DRG's electrodynamic system and a reduced effective thickness of the interaction space. The effective electron flow thickness Δ_{eff} is defined as:

$$\Delta_{eff} = d_0 - \beta, \tag{1}$$

where d_0 – the period of the slow-wave system, β=v/c – the relative velocity of the EB, i.e., the deceleration factor.

For parameters λ = 0.8 mm and β = 0.1, Δ_{eff} = 0.025 mm. It has been suggested that improving the generator's output characteristics in the submillimeter range requires ultra-thin sheet EBs ($\Delta_{EB} << 0.03$ mm) with increased current density [8]. For thicker beams ($\Delta_{EB} > \Delta_{eff}$) at wavelengths λ < 1 mm, an increase in β —achieved by using higher accelerating voltages—is necessary to maintain efficient energy conversion.

However, these calculations do not account for changes in the structure of the static electron flow within the DRG or Clinotron interaction space, where electrons in the beam move near the surface of the diffraction grating, which is at a high anode potential. Additionally, a significant challenge remains in developing generators for the submillimeter range that can operate with ultra-thin EBs within the interaction space.

C. Possible Solutions

Therefore, investigating new mechanisms and methods for efficiently converting the energy of thick EBs into electromagnetic oscillations in Clinotrons and DRGs operating in the millimeter and submillimeter wavelength ranges is of great importance. A promising approach involves utilizing a non-uniform (profiled) focusing magnetostatic field [7]. In this configuration, electrons from the upper layers of the thick EB are redirected toward the lower layer of effective thickness Δ_{eff}, located near the surface of the diffraction grating. This redistribution enhances the interaction between the thick electron beam and the electromagnetic oscillation field excited in an open resonator, thereby reducing the starting current and increasing the generator's output power [6]–[9].

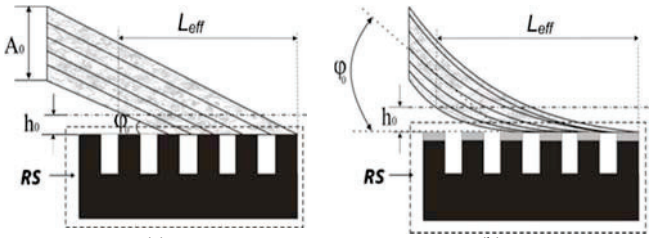

Fig. 3. EB trajectories in DRGs and Clinotrons: (a) in a uniform magnetic field; (b) with a dielectric layer applied to the periodic system; RS — Retarding system; A_0 is the thickness of the EB; h_0, L_{eff} — effective thickness and interaction length of the EB with the field; φ_0 inclined injection angle in Clinotrons and DRGs.

Furthermore, applying a thin dielectric layer to the SWS surface induces an induced braking electric field as the electron beam (EB) deposits onto the layer. Under this influence, the trajectory of the EB becomes parabolic (Fig. 3b). This modification enhances interaction efficiency between the beam and the SWS field, improving energy transfer and thereby increasing both generation power and overall device efficiency [4], [5]. The resulting effect is comparable to that achieved with a non-uniform magnetic focusing field.

A similar approach can be used to expand the beam-field interaction space, further enhancing power output. This method applies to all devices utilizing the 'Clinotron' mode, where the EB is introduced into the interaction space with the slow-wave field to optimize efficiency and performance in the millimeter and submillimeter wavelength ranges.

III. EB Dynamics in a BWT and DRG with a Dielectric-Coated SWS

A. Mechanism of the Effect of Dielectric-Coated SWS on EB

In a Clinotron or DRG, the EB is directed at an angle φ_0 to the SWS (Figs. 1–3). With a dielectric coating, part of the EB deposits onto the surface, forming a braking potential that influences the EB and alters its trajectory. In the absence of a magnetic field, where the electric field has only one component, the system of equations can be written as:

$$\begin{cases} m\frac{dv_x}{dt} = 0 \\ m\frac{dv_y}{dt} = -eE_y \\ m\frac{dv_z}{dt} = 0 \end{cases}, \tag{2}$$

where v_x and v_y are the horizontal and vertical components of velocity, m and e are the mass and charge of the electron, and E_y is the intensity of the electric field generated by the deposition of the EB on the SWS.

After integrating the equations with the given initial conditions [8], we obtain a system of parametric equations describing the motion of an electron in the braking field:

$$\begin{cases} x = v_x t \\ y = \alpha h_0 - v_y t + \frac{a}{2} t^2 \end{cases}, \quad (3)$$

where $a = \frac{eE_y}{m}$ is the acceleration caused by the field generated by the electrons deposited on the dielectric substrate of the SWS, and $\alpha\, h_0$is the impact parameter. For practical calculations, we assume $\alpha \approx 1$, meaning the center of the electron-optical system is located at the boundary of the slow-wave field, which exponentially decays from its surface. However, for simplicity, we assume that it remains constant from the SWS surface up to a height of h_0.

As seen from equation (3), the trajectory of electron motion becomes parabolic, whereas in the classical case (Clinotrons and DRGs), where $a = 0$, it remains linear. Consequently, the interaction space of the EB with the surface wave field of the SWS is limited in length [6]–[9]:

$$L = \frac{h_0}{\sin\varphi_0} + \frac{A_0}{\mathrm{tg}\varphi_0} \quad (4)$$

where A_0 is the EB thickness, h_0 is the thickness of the layer where effective energy exchange occurs between the SWS field and the EB, and φ_0 is the EB inclination angle to the SWS. As the inclination angle increases, EB-SWS interaction is enhanced, leading to increased power generation. However, this also reduces the length of the interaction space, which, at some point, decreases the generated power.

The presence of these two competing mechanisms results in optimal inclination angles for an EB moving linearly in a uniform focusing magnetic field (approximately 6 to 12 arc minutes). The sensitivity of the beam injection angle into the interaction space complicates tuning the device for optimal generation mode, thereby affecting maximum power generation and efficiency.

When a braking electric field is applied, the electron trajectory becomes more gradual. If the potential of the dielectric substrate fully compensates for the vertical velocity component $v_y = v_0 sin\varphi_0$, where $v_0 = \sqrt{\frac{2eU_0}{m}}$ is the electron velocity and U_0 is the accelerating potential (typically 3.5–5 kV for the millimeter range), the braking potential will be approximately $U_y \approx U_0\, sin^2\varphi_0$. This implies that relatively small braking field values, on the order of tens of volts, are required. As the braking potential increases from zero, the initially linear EB trajectory gradually extends due to its parabolic shape. This increases the interaction space length up to four times compared to classical devices. Since output power grows exponentially with the interaction length in the SWS field, this results in a significant increase in generator power and efficiency.

The effective EB-SWS interaction space in the millimeter range (1 mm to 10 mm) has a thickness of approximately 0.031 to 0.31 mm. To ensure efficient energy exchange between the EB and the slow wave, the slow-wave system (SWS) in millimeter and submillimeter-wave generators must span at least 25 to 40 slow-wave periods, corresponding to a length of approximately 25 to 40 mm, which represents the current technological limit. The size constraints of the SWS determine the minimum allowable inclined injection angle in Clinotrons and DRGs. As the wavelength decreases and enters the submillimeter range, the inclination angle φ_0 can drop below 0.1 degrees. Increasing the EB thickness necessitates a longer SWS, but in the submillimeter range, the beam thickness should not exceed 0.1 mm. At such small angles, the total and horizontal dimensions of the effective interaction space become nearly identical.

IV. Design Options for Periodic SWSs in BWTs and DRGs with Dielectric Coatings

In this section, we explore three configurations (see Figs. 4, 6, and 7) of periodic SWSs in Clinotrons and DRGs that incorporate dielectric coatings to enhance EB interaction.

A. Periodic SWS Designs

Configuration 1 (C1): *Reflective Diffraction Metal Grating with Dielectric Coating*. This design features a reflective diffraction metal grating with a dielectric layer applied to its upper surface (Fig. 4). The dielectric layer facilitates the drainage of electrons deposited on its surface, forming a braking electric field that alters the electron beam's trajectory, increasing the interaction length with the SWS and improving overall device efficiency.

Configuration 2 (C2): *Dielectric-Insulated Reflective Diffraction Metal Grating with Parallel Leakage Resistance and Capacitance.* In this configuration, the SWS consists of a reflective diffraction metal grating placed on a dielectric substrate, electrically insulating it from the vacuum-tight housing (Fig. 5). A leakage resistance and capacitance are connected in parallel between the grating and the housing. This setup regulates the discharge time constant of the charge field, controlling the EB trajectory and enhancing energy transfer.

Configuration 3 (C3): *Strip Metal Grating with Dielectric Layer and Metal Screen*. Here, the SWS is designed as a strip metal grating placed on a dielectric layer with a specific thickness ($h_{eff} = \lambda_1/4 + n\lambda_1/2$, where λ_1 is the wavelength in the dielectric, and n = const = 0, 1, 2…), with a metal screen located underneath (Fig. 6). Electrons deposited on the grating elements create a field that alters the electron trajectory, extending it and improving interaction with the SWS field. This design enhances device performance by increasing the interaction space without increasing physical dimensions.

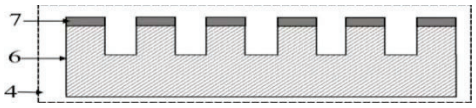

Fig. 4. SWS with a dielectric layer.

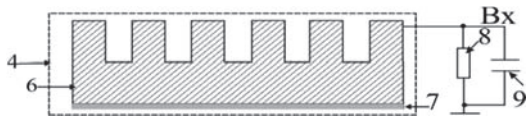

Fig. 5. SWS isolated from the case by a layer of dielectric.

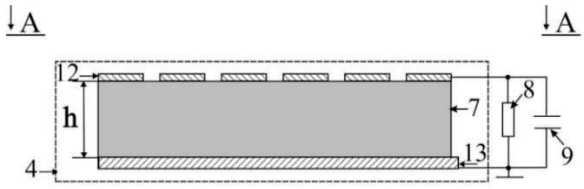

Fig. 6. Ribbon SWS.

B. EB Interaction with SWS

The EB is emitted from the cathode through the electron-optical system (2) (Figs. 1, 2), forming a paraxial sheet EB (3). This beam propagates along the magnetic field lines of the focusing magnetic field at a small angle (~6–12 arc minutes) to the interaction surface of the SWS (4). When the EB deposits some of its electrons onto the dielectric layer (7) of SWS — either applied to the reflective diffraction grating (6) (refer to C1, Fig. 4) or placed between the strip metal grating (12) and the metal screen (13) (refer to C3, Fig. 6)— a negative charge is formed on the surface of the dielectric layer. The EB, moving through the potential field of this charge, is deflected away from SWS. The degree of deflection increases as more electrons accumulate on the dielectric layer, thus enhancing the negative potential on the SWS.

Charge leakage from SWS occurs due to leakage resistance, a result of the imperfect characteristics of the dielectric layer. This resistance can be controlled by selecting dielectric materials with specific electrical properties, such as dielectric constant and loss tangent. In configurations where SWS is a reflective diffraction metal grating (6) (refer to C2, Fig. 5), charge from the dielectric layer is discharged onto the grating. The deposition of the EB onto SWS increases the negative potential, causing further deflection of the beam. However, as charge leakage occurs, the potential decreases, leading to a reduction in beam deflection. The leakage resistance (8) provides a path for charge dissipation from SWS in various configurations (refer to C2, C3, Figs. 5, 6), connecting the strip metal grating (12) to the metal screen (13) and the vacuum-tight housing (1). In parallel with the leakage resistance (8), the capacitance (9) regulates the charge dissipation time constant for the EB.

Over time, a dynamic equilibrium is established, where the rate of charge deposition onto SWS equals the rate of charge leakage. As a result, the trajectory of each electron in the EB becomes more gradual, allowing the electron to remain longer in the braking field of the negative harmonic of the EMW in SWS. This ensures more efficient energy transfer from the EB to the electromagnetic field of the SWS.

Ultimately, utilizing dielectric coatings in the SWS successfully resolves the issue of controlling the EB injection angle into the interaction space. It also increases the effective length of the interaction region between the EB and the electromagnetic field of SWS, thereby improving the generation efficiency and overall performance of the device.

V. Discussion

The use of dielectric coatings on periodic SWSs for Clinotrons and DRGs, as explored both theoretically and experimentally, presents a promising solution to enhance the power conversion efficiency, particularly in the millimeter and submillimeter-wave ranges. The inclined EB injection into the periodic SWS, such as a comb structure, improves the interaction between the EB and the high-frequency field, thereby increasing energy transfer efficiency and output power.

However, while this approach shows clear advantages, the practical application of dielectric coatings introduces several complexities. Theoretical models suggest that optimal coating materials and thicknesses are essential for maintaining effective EB interaction and preventing issues such as impedance mismatching and charge depletion. Experimentally, the performance gains depend on the precise alignment of the EB with the SWS and the careful management of coating properties to minimize energy loss. Moreover, challenges in scaling to THz frequencies, where the required current densities and EB thicknesses become more demanding, highlight the need for further research into advanced coating technologies and the integration of these materials within the constraints of current fabrication techniques.

Thus, while dielectric coatings offer a viable pathway for improving BWT and DRG performance, continued refinement of both theoretical models and experimental designs is crucial for overcoming existing technological limitations.

VI. Conclusion

Thin-film dielectric coatings on SWS in BWTs and DRGs improve EB interaction and efficiency by modifying the EB trajectory and expanding the interaction region without increasing system size. Optimizing dielectric properties like permittivity and loss tangent is essential for precise braking field control. Future research should balance material performance and system complexity to boost efficiency

***Abstract*—This paper presents the results of a study on the feasibility of automatically testing software for compliance with accessibility standards. Such testing is typically performed during the functional testing phase. The relevance of this work stems from the need to ensure that a software's visual elements adhere to accessibility guidelines, including those for users with color vision deficiencies. We analyze the problem, propose a mathematical model for evaluating images against accessibility criteria, and present a methodology for automatic testing using computer vision libraries (OpenCV). We also report the results of testing a prototype tool designed to assess visual elements for color vision impairments. Finally, we discuss how these results can be integrated into continuous integration (CI) systems to automatically detect potential accessibility issues.**

***Index Terms*—accessibility testing, computer vision, functional testing, color vision deficiencies, continuous integration**

I. Introduction

The digitalization of nearly all aspects of daily life has made software accessibility a fundamental requirement. As public services, finance, education, healthcare, and entertainment increasingly move online, the need to accommodate users with visual impairments, including color vision deficiencies (CVD), has grown. Globally, around 1% of women and up to 8% of men experience color perception issues according to Simunovic [1], impacting their ability to use digital services safely and efficiently. Insufficient attention to accessible environmental cues—such as the absence of audible traffic lights, tactile paving, or proper color-contrast settings—significantly increases the physical vulnerability of people with visual impairments [2].

Regulatory frameworks in the European Union, the United States, Ukraine, and beyond—such as the Americans with Disabilities Act (ADA), Section 508, the European Accessibility Act (EAA), and the Ukrainian National Strategy for Creating a Barrier-Free Space—mandate that digital content and services be accessible to people with disabilities, in line with the Web Content Accessibility Guidelines (WCAG) 2.2. These guidelines, based on the POUR principles (Perceivable, Operable, Understandable, Robust), set criteria to ensure that information is not conveyed by color alone, interfaces are keyboard-accessible, content is clear, and technologies remain compatible with assistive tools.

While regulations often focus on public-sector services, the commercial sector faces increasing demand for compliance due to legal risks and user expectations. In practice, accessibility testing now extends beyond manual inspection to automated analysis using AI and computer-vision techniques, especially during functional testing. Automated tools can check color contrast, simulate different types of color blindness, and suggest alternative information channels (e.g., text labels or symbols).

This is particularly relevant for computer games and interactive applications, where color frequently encodes critical information (health bars, navigation cues, object highlights). Recent advances allow testing not only of static screens but also of dynamic and video content, making CI-based accessibility checks feasible.

This paper focuses on methodologies for automated accessibility-compliance testing, particularly for users with CVD. We review the regulatory context, examine state-of-the-art tools and approaches, and present a framework for automated testing using computer vision. Special attention is given to the challenges of testing in interactive and rapidly changing visual environments.

II. Publications and Tools review

A. Publications review

Early identification and remediation of CVD barriers benefit both users and developers: they broaden the potential audience and reduce costly post-release fixes. Automated accessibility testing workflows—spanning simple simulators, contrast checkers, rule-based scanners, heuristic evaluators, and emerging AI-driven algorithms—offer scalable methods to detect and guide the correction of color-related issues.

Color drives usability but poses barriers for those with color vision deficiencies (CVD)—anomalies in the red, green, or blue cones—affecting approximately 8% of men and 0.5% of women (Table I). With no cure for congenital CVD, designers rely on automated tools—simulators, contrast checkers, rule-based scanners, heuristics, and AI—to identify and address color issues.

1) Assistive image-processing systems

Feng et al. [3] apply a hue-rotation of the H channel in HSV space via OpenCV to improve color discriminability for achromat observers, though they report reduced effectiveness in natural scenes with complex palettes. Meng et al. [4] present a Raspberry Pi-based prototype that performs HSV thresholding, color filtering, and on-screen text feedback; however, it was evaluated only on controlled color patches and benchmark shapes, lacks support for dynamic content (animations or game frames), offers no integration into web/mobile or design tools, and provides no performance metrics for real-time use.

2) Simulation and heuristic-based evaluation

Bonacin et al. [5] propose an ontology-driven framework for per-user recoloring. Angerbauer et al. [6] report on a large-scale, crowd-sourced evaluation of academic figures under CVD simulations. Alcaraz-Martínez et al. [7] develop 18 heuristics to evaluate statistical charts for CVD and low-vision users. These approaches are valuable but typically require expert or crowd validation, demand ongoing maintenance as standards evolve, and suffer from variability in subjective ratings.

3) Automated contrast and rule-based checkers

Jamil et al. [8] compared OS high-contrast modes with custom "CVD themes," finding that although high-contrast settings improve text legibility, they often degrade aesthetic appeal and remove visual context. Ara et al. [9] survey existing automated accessibility tools—classifying them as declarative, ontological, algorithmic, or hybrid—and reveal that only 13% support end-to-end automation. They further observe that most tools focus on basic WCAG contrast checks and omit non-text elements (such as charts and icons); that rule-based methods lack semantic understanding (resulting in false positives and negatives); that ontological approaches require continuous maintenance; and that fixed thresholds fail to account for individual CVD variations.

4) Impact on user experience and performance

Napoli & Chiasson [10] conducted an empirical study with the Spectrum Chrome plugin in the browser game *Pet Rescue Saga*, finding that while some players maintained accuracy and completion times, most reported increased difficulty and reduced confidence under CVD simulation. Tillem & Gün [11] survey the gaming accessibility literature, noting that although performance impacts vary, users with CVD consistently report poorer subjective experiences and call for improved design guidelines. Wang et al. [12] introduce the "Color Blindness Bartender" VR app—which maps RGB to LMS and applies matrix-based color removal—and show via task-accuracy scoring that VR is effective both for educating sighted users about CVD challenges and for prototyping more accessible interfaces.

5) Screening and diagnostic tools

Fliotsos et al. [13] compare the Eye Handbook mobile app to Ishihara plates in full-color, grayscale, and red-green simulation modes, finding overall parity but plate-specific discrepancies. Abbas et al. [14] develop an Android application with seven assessment modules (color detection, object size, motion, visual field), though they omit detailed accuracy and clinical validation metrics. Laskowski [15] presents a four-stage HTML5/JavaScript screening game tested on 143 participants; while an error threshold reduced false positives, further calibration for sensitivity versus specificity and longitudinal validation remain necessary.

B. Tools Review

A variety of tools support automated CVD accessibility testing (Table II). Desktop simulators like Color Oracle offer static filtering in four CVD modes but lack video or real-time integration. Mobile apps such as Chromatic Vision Simulator provide live camera-based filters for all major types but cannot process recorded gameplay. Additional aids include Sim Daltonism, WebAIM Contrast Checker, and built-in OS color filters—each useful yet limited in automation, scope, or integration.

Despite a growing toolkit for CVD accessibility testing, significant gaps remain. Current solutions largely ignore non-text elements such as charts, maps and complex graphics, and they apply one-size-fits-all rules without adapting to individual user profiles. Promising hybrid human-AI approaches (e.g.,

TABLE II. COMPARISON OF CURRENT TOOLS AND TECHNOLOGIES FOR AUTOMATED COLOR VISION DEFICIENCY ACCESSIBILITY TESTING

Tool	Type	Features	CVD Support	Automation	Limitations
Color Oracle	Simulator	4 CVD modes	All types	Manual	No reports
WebAIM Contrast Checker	Contrast checker	WCAG contrast	General	Semi-auto	Text only
WAVE / Axe / Lighthouse	Scanner	WCAG audits	General	Full-auto	Limited scope
Daltonization algorithms	Recolor filter	Hue shifting	Prot/Deut	Auto	High cost
colorBrewer / VizPalette	Design aid	Safe palettes	Common types	Semi-auto	No testing

crowd-sourced evaluations) have yet to be integrated into developer workflows, and there is little support for embedding CVD checks directly into IDEs, design tools or CI/CD pipelines. Finally, the field lacks large-scale, longitudinal studies to validate automated methods against real user outcomes and drive future improvements.

III. THEORETICAL BACKGROUND OF BUILDING AN AUTOTESTING SUBSYSTEM

To simulate different types of color blindness, the choice of color space is crucial. Typically, in computer systems, images are stored in the sRGB format, where each element represents the value of one of the colors: red (R), green (G), or blue (B) for each pixel of the image. The screenshots of the image are stored as a matrix that encodes the color of each pixel.

To process the image in the context of dichromacy or trichromatism simulation, it is necessary to convert the image from RGB format to the LMS color space. This space is based on the reactions of three types of photoreceptors in the human eye:

- L: receptors sensitive to long wavelengths (red),
- M: receptors sensitive to medium wavelengths (green),
- S: receptors sensitive to short wavelengths (blue).

Converting the image from one color space to another is necessary to model color vision deficits. For instance, protanopes, deuteranopes, and tritanopes lack L-, M-, or S-cone receptors, respectively. Therefore, a natural approach to simulating dichromacy is to convert the image to the LMS color space and remove the component corresponding to the absent receptors. The conversion from RGB to LMS is achieved using a linear transformation (matrix multiplication), and there are multiple ways to perform this process [16], [17].

The conversion from sRGB to linear RGB is performed by removing the gamma correction applied in the sRGB color space. For each component C_{sRGB}, the conversion to linear RGB C_{linear} is given by:

$$C_{linear} = \begin{cases} \frac{C_{sRGB}}{12.92}, & \text{if } C_{sRGB} \leq 0.04045, \\ \left(\frac{C_{sRGB}+0.055}{1.055}\right)^{2.4}, & \text{if } C_{sRGB} > 0.04045. \end{cases} \quad (1)$$

This formula ensures that the gamma-corrected sRGB values are converted back to a linear space for accurate processing.

The formula for converting from RGB to LMS is as follows (based on [16], [17]):

$$\begin{bmatrix} L \\ M \\ S \end{bmatrix} = \begin{bmatrix} 0.31394 & 0.63957 & 0.04652 \\ 0.15530 & 0.75796 & 0.08673 \\ 0.01772 & 0.10945 & 0.87277 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix}, \quad (2)$$

where L, M, and S represent the long, medium, and short wavelength cone responses, and R, G, and B represent the red, green, and blue components in the RGB color space. The reverse conversion (LMS to RGB) is performed using the inverse matrix:

$$\begin{bmatrix} R \\ G \\ B \end{bmatrix} = \begin{bmatrix} 5.4722 & -4.6416 & 0.1694 \\ -1.1252 & 2.2939 & -0.1679 \\ 0.0298 & -0.1932 & 1.1636 \end{bmatrix} \begin{bmatrix} L \\ M \\ S \end{bmatrix}. \quad (3)$$

After converting the original image (1, 2), we get the color in the LMS space by replacing the value of one of the waves depending on the type of trichromacy or dichromacy with the help of defined color matrices. Thus, depending on the specified type of dichromacy (protanopia, deuteranopia, or tritanopia), we simulate how color perception changes. For protanopia and deuteranopia, a plane is calculated that reflects the perception of red, green, and blue colors, and a color conversion is applied within this plane. For tritanopia, a similar process is used, but for the perception of red, green, and yellow.

After simulating the selected type of dichromacy or trichromacy, the image colors are converted back to RGB/sRGB (3) or another format for display and further visual analysis.

In the LMS color space, colors that differ only in the component associated with the missing receptor cannot be distinguished by a dichromat. This leads to the formation of the so-called “confusion lines,” which are parallel to the axis of the missing receptor in the LMS space. According to this model, protanopes cannot distinguish between colors that differ only in the L-component, deuteranopes—in the M-component, and tritanopes—in the S-component.

To illustrate this phenomenon, we plotted graphs showing several confusion lines in LMS space alongside their corresponding representations in RGB space for both deuteranopia and tritanopia. As a source image, we used a full-color photograph of tulips against a blue sky, which provides a rich

variety of hues and gradations and thus clearly demonstrates the effects of color blindness.

For sRGB color space it represents intensity a color in the range from 0 to 1, for LMS color space it represents the response of cones sensitive to a wavelength in the human eye.

At first glance, the colors look different and are very easy to distinguish (Fig. 1). But if we apply a deuteranopia lens, we get colors that are very similar to each other (Fig. 2).

- RGB Space: All three trajectories bend and converge toward the G and B axes, forming nearly parallel paths;
- LMS Space: Points collapse along the confusion axis (L–S), forming thin, almost straight ribbons—explaining why observers with green-cone deficiency cannot distinguish "blue→magenta", "blue→pink", or "green→yellow".

An even more striking illustration is provided by the tritanopia simulation (Fig. 3), where in RGB space the confusion lines tilt toward the blue (B) axis, and in LMS space collapse along the S axis, rendering the "blue→yellow" gradients virtually indistinguishable.

IV. Implementation and Testing

The testing program architecture consists of five main modules:

- Image processing: This class deals with the preparation and subsequent storage of the image result. The main functions are converting the image from BGR space to RGB space, scaling the image (if necessary), converting the image to BGR space from RGB space for correct saving. It interacts with the interface class, taking input data for working with the image and simulation, and also sends the image with a lens for previewing to the interface field. It also interacts with the simulation class by passing images for applying the color blindness lens.
- Video processing: The component divides the video into frames and records the result in a separate video with the applied lens. The main functions are converting video to an array of images, converting each image from BGR space to RGB space for lens application. It interacts with the interface class, taking input data to work with video and simulation. It also interacts with the simulation class by passing each frame for color blindness lens application in a group of 10 frames at a time to speed up the lens application.
- Processing the region around the cursor: This class captures a specific region around the cursor and applies a color blindness lens to it. Its main functions are to capture a region of the screen every few milliseconds and apply a lens to the captured image. It interacts with the UI class, taking input data to work with the simulation, and when the image simulation is complete, displays the image in a special user interface element. It also interacts with the simulation class by passing each image to a region of the screen and applying a color blindness lens to it.
- Interface: This class stores all the information provided by the user and also allows changing the interface settings for people with visual impairments. It interacts with all three image processing classes, passing the input data to them.

To implement the system, we chose the Python3 programming language, OpenCV for image processing, Matplolib for debugging, and other necessary libraries such as NumPy. We also use Tesseract to work with text.

A. Testing Text Fragments

To analyze the desired text, we first get the RGB values of the background and text color channels. Then we divide each color by 255. Next, we find the linear value of the color: if the color value is less than or equal to 0.03928, then its linear value is the division of the color value by 12.92, and if it is greater, then add 0.055 to the color value, then multiply the result by 1.055 and raise this number to a power of 2.4::

$$f(c) = \begin{cases} \frac{c}{12.92}, & \text{if } c \leq 0.03928, \\ \left(\frac{c+0.055}{1.055}\right)^{2.4}, & \text{if } c > 0.03928. \end{cases} \tag{4}$$

After that, multiply the red color by 0.2126, the green by 0.7152, and the blue by 0.0722. Now you need to check which value is larger—the background or text value. Add 0.05 to each value and divide the larger value by the smaller one. The result will be the contrast ratio between the two colors. The value must be greater than 3 if it is a headline and greater than 4.5 if it is plain text.

Automatic testing of text fragments, especially for computer games, is a complex task that can be addressed by training artificial neural networks to extract text fragments and subsequently process them with predefined algorithms to determine readability, color contrast ratio, and more. Currently, this functionality is only implemented for manual testing.

Optionally, it is possible to analyze text fragments for colors compliance using text fragment screenshots in the current implementation.

B. Testing Image Colors

We use the classic Viénot-Brettel-Mollon [18], Machado et al. [19], and Brettel et al. [20] algorithms for CVD simulation, as they remain widely used and produce accurate results.

To process an image or video, first load it with `cv2.imread(path)`, which returns a NumPy array of pixel values in BGR order. For CVD simulation, convert BGR to RGB before applying the filter, then convert back to BGR before saving.

When processing a video, apply the same procedure to each frame and write the results to a new video file. The key challenge is selecting the region containing text or other elements to test; once selected, the algorithm crops that region and applies the chosen CVD filter.

We support four types of red-green simulations: deuteranopia, deuteranomaly, protanopia, and protanomaly. After

Fig. 1. Source image sRGB and LMS color spaces.

Fig. 2. Deuteranopia lens applied to sRGB and LMS.

Fig. 3. Tritanopia lens applied to sRGB and LMS.

capturing an image or frame, the CI-script chooses the simulation algorithm. For deuteranopia and protanopia, we use the Viénot-Brettel-Mollon method; for deuteranomaly and protanomaly, we use Machado et al.'s model, with a severity parameter (1.0 for full dichromacy, less than 1.0 for anomalous trichromacy).

For blue-yellow simulations (tritanopia and tritanomaly), we apply the Brettel et al. algorithm. No model can perfectly replicate another person's perception, so each algorithm offers an approximation of CVD vision.

To implement automatic testing, the following steps were taken:

- Determine the number of color clusters in LAB space (e.g., 10), potentially normalizing image sets to align palettes.
- Convert images from sRGB to LAB.
- Segment images in LAB space using KMeans (scikit-learn).
- Apply color masks and compute the percentage of pixels in each cluster.
- Simulate color blindness by applying the corresponding filters (e.g., protanopia, deuteranopia).
- Optionally apply additional processing algorithms.
- Output and/or log results, including graphical summaries (e.g., Fig. 3 and Fig. 4).

Based on expert analysis, a threshold of 40 was chosen to flag images that may violate accessibility standards. This reduces false positives and accelerates testing. It also enables

fully automated testing within CI pipelines.

CONCLUSIONS

This paper analyzes the current state of software development with respect to accessibility standards for users with color vision deficiencies. This issue is particularly significant for software targeting European (including Ukrainian) and North American markets, where 7-9% of the population is affected by CVD [21]. We propose an automated testing approach that transforms images from sRGB to LAB color space, applies clustering, and computes an integral indicator based on the percentage of colors falling into critical zones (yellow-red and blue-green).

A prototype implementation has been developed and tested, demonstrating the feasibility of integrating the proposed method into CI workflows.

Future research will focus on automating color-contrast testing of text in screenshots—especially in applications such as computer games, which often feature low-contrast textual elements—and on integrating neural-network-based algorithms (e.g., CUD-Net [22]) as modules in CI systems for continuous accessibility validation.

***Abstract*— This paper explores the need for effective acoustic detection of unmanned aerial vehicles (UAVs), focusing on mitigating background noise interference and enhancing signal-processing algorithms. Simulation modeling evaluates acoustic direction-finding systems under varying noise conditions, demonstrating high detection accuracy at favorable signal-to-noise ratios (SNR), with performance degrading as noise increases.**

Keywords*— acoustic detection, UAV localization, noise interference, bearing estimation, cross-correlation, SNR, simulation modeling, time delay estimation.

I. Introduction

The early development of unmanned aerial vehicle (UAV) technology dates back to the early 20th century, when UAVs were primarily employed for military reconnaissance and surveillance. Over the past several decades, rapid technological advancements have enabled UAVs to expand into diverse civil and commercial applications— ranging from agriculture and disaster management to environmental monitoring and journalism. However, the dramatic increase in UAV deployment has raised significant concerns regarding airspace safety, privacy, and public security [1].

Traditional detection approaches based on radar, optical, and radio frequency (RF) methods have proven effective under certain conditions but often face limitations in adverse weather, low visibility, and electromagnetic interference. In contrast, acoustic detection techniques offer a passive, cost-effective alternative by exploiting the unique sound signatures generated by UAV propulsion systems and aerodynamic interactions [2]–[7]. Acoustic sensors operate independently of light and are generally less susceptible to RF interference; however, their performance is challenged by ambient noise and complex environmental conditions, which can lead to errors in direction-of-arrival (DOA) estimation and target classification.

Recent research has focused on enhancing acoustic detection through advanced signal processing and machine learning methods. For instance, adaptive filtering combined with deep learning-based denoising has shown promising improvements in low signal-to-noise ratio (SNR) environments [8], [9]. Additionally, simulation modeling of acoustic direction finders has become a critical area of study, enabling the optimization of sensor array configurations and real-time processing algorithms for robust UAV detection.

In this work, we present a comprehensive simulation modelling study and performance analysis of acoustic direction-finding systems (DFSs) specifically designed for small UAVs. We evaluate both parametric and non-parametric signal processing approaches under various noise conditions to assess detection accuracy and localization performance. By integrating insights from the latest publications and state-of-the-art techniques, our study contributes to the development of robust acoustic detection systems capable of operating effectively in challenging real-world scenarios.

II. Theoretical Basic of Acoustic Direction Finding

Acoustic direction finding exploits the propagation delays of sound waves captured by an array of microphones positioned at known distances. When a sound wave impinges on the array, the time delay between the signals received by individual microphones depends on the angle of incidence. This delay is directly related to the bearing—or azimuth—of the sound source.

Fig. 1 shows a schematic diagram of an acoustic DFS with two microphones, M_0 and M_1, oriented at a specified angle relative to the x-axis. The time delay τ between the signals received by M_0 and M_1 is used to estimate the azimuth α of the source O relative to the baseline connecting the sensors. Mathematically, the time delay τ between two microphones separated by a baseline distance d can be expressed as

$$\tau = d/v \sin(\alpha), \quad (1)$$

where v denotes the speed of sound in air and α is the angle between the DOA and the normal (perpendicular) to the baseline connecting the microphones, as shown in Fig. 1.

By inverting (1), the azimuth α of the sound source can be determined from the measured delay:

$$\alpha = \arcsin(c\tau/d). \quad (2)$$

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

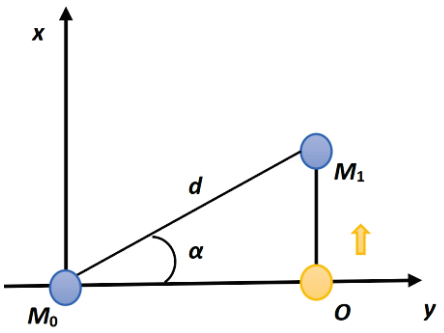

Fig. 1. Schematic diagram of an acoustic DFS consisting of two microphone M_0 and M_1

Prior studies [10]–[13] have demonstrated that the minimum possible bearing error in acoustic DFSs increases as the source direction deviates from the baseline normal, following an inverse cosine relationship, specifically proportional to $1/\cos(\alpha)$. For instance, a deviation of 60° from the baseline normal effectively doubles the error. Consequently, to maintain acceptable accuracy, these systems typically operate within sectors of ±60° from the baseline normal, encompassing a total angular range of 120° [10], [11].

III. DESIGN AND IMPLEMENTATION OF SIMULATION EXPERIMENTS FOR EVALUATING THE PERFORMANCE OF ACOUSTIC DFSS

In this section, we describe the simulation experiments designed to evaluate the bearing accuracy of our acoustic DFS. The step-by-step flow map of the experimental design for evaluating acoustic DFSs is shown in Fig. 2. The system uses two orthogonally oriented microphone arrays, and the experiments focus on assessing the effect of signal-to-interference ratios (SIRs) and the efficacy of our correction method on bearing estimation. More detailed descriptions of the experimental setup, signal preparation, noise modeling, performance evaluation and simulation results are provided in the following subsections.

A. Signal Acquisition and Preprocessing

The simulation models an acoustic DFS that employs two crossed microphone arrays positioned at a 90° angle. Each array consists of four microphones, with inter-element spacings of 0.5 m and 1 m, respectively. The azimuthal bearing is estimated by computing the time delay between microphone pairs via cross-correlation. For each pair, the cross-correlation function (CCF) is computed over a segment of N_0 samples, and the time delay corresponding to the maximum value is used to derive the bearing. The CCF is defined as:

$$R_{\max}(k) = \max_{k} \sum_{i=lN_0}^{(l+1)N_0} S_1(i)\, S_2(i+k) \qquad (3)$$

where $S_1(i)$ and $S_2(i+k)$ represent are the signals from the first and second microphones, respectively, k represents the time shift between these two microphones/channels in samples, l is the segment number, and $R_{\max}(k)$ is the maximum value of the CCF, which is achieved with a shift of k samples.

In this study, acoustic signals from UAVs were recorded at a sampling frequency of 44.1 kHz. To simulate the object's bearing, an artificial delay was introduced in one channel. Four scenarios were designed to evaluate the performance of the DFS under different conditions (as illustrated in Fig. 2):

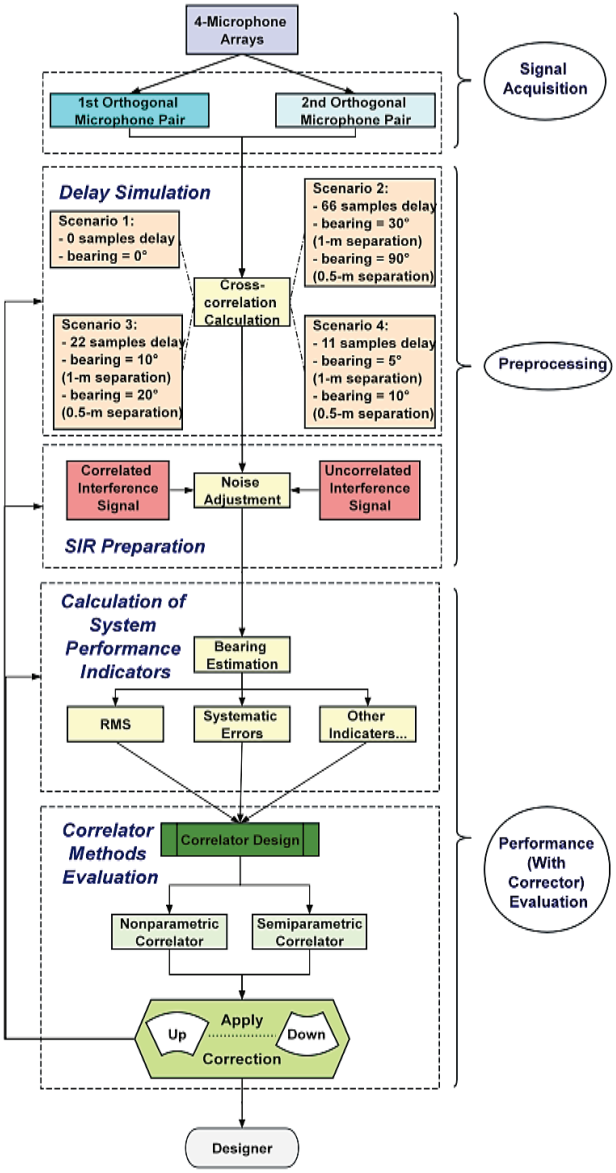

Fig. 2. Flow Map of the Experimental Design for Evaluating Acoustic DFSs

Scenario 1 (S1): The signals from both channels/ microphones have no time difference, representing an object positioned perpendicular to the centre of the microphone array (bearing = 0°).

Scenario 2 (S2): The second channel signal is delayed by 66 samples relative to the first. This corresponds to a bearing of approximately 30° for microphones with a 1-meter separation and 90° for those with a 0.5-meter separation.

Scenario 3 (S3): The delay between channels is 22 samples, corresponding to a bearing of approximately 10° for a 1-meter separation and 20° for a 0.5-meter separation.

Scenario 4 (S4): The second channel is delayed by 11 samples, corresponding to a bearing of approximately 5° for a 1-meter separation and 10° for a 0.5-meter separation.

The next step in signal preparation involved adding the interference signal to the desired signal to obtain a resulting signal with a specified SIR. This was done by forming an additive mixture of the signal and interference:

$$U_i = S_i + n_i\,, \tag{4}$$

where the acoustic signals of the useful object, S_i, and wind noise, n_i, have respective variances:

$$\langle S_i^2 \rangle = \sigma_S^2,\ \langle n_i^2 \rangle = \sigma_n^2. \tag{5}$$

The SNR is given by:

$$\mu_0 = \frac{\sigma_S^2}{\sigma_n^2}\,. \tag{6}$$

To achieve the required SNR, μ, the following condition must be met:

$$\mu = \mu_0\, K_0^2 \tag{7}$$

where K_0 is the correction factor by which the interference signal is scaled. This factor is given by:

$$K_0 = \sqrt{\frac{\mu}{\mu_0}}. \tag{8}$$

The desired SIR is achieved by either adjusting the useful signal before mixing or applying a correction factor to the interference signal prior to addition.

In this study, the next step in signal preparation involved adding interference to the useful signal to maintain a specified SIR, with a particular focus on the impact of wind noise, which exhibits significant non-stationary and non-Gaussian characteristics. Specially, two scenarios were considered:

Correlated Interference: The interference is identical in both direction-finding channels, enabling accurate estimation of the object's direction. The useful signals in both channels remain the same, differing only in time delay. The interference is adjusted accordingly to maintain the desired SIR.

Uncorrelated Interference: Independent interference signals are generated for each channel. Correction factors are computed separately for each segment using equation (8) to ensure equal SIRs in both channels before performing direction-finding calculations.

The study analyzed RMS and systematic errors in direction estimation, both with and without correction. The simulation results, involving wind noise (in the absence of gusts) as correlated and uncorrelated interference, are presented in the following two subsections: (1) without the corrector and (2) with the corrector.

B. Simulation Results Without Corrector

Simulations were conducted in MATLAB using segment lengths of 4096, 16,384, and 32,768 samples, corresponding to time durations of 92.9 ms, 0.327 s, and 0.743 s, respectively, across four scenarios (S1, S2, S3, S4). To account for variations in noise characteristics, noise components were categorized based on their homogeneous properties, simulating the DFS under both gusty and calm wind conditions. Bearing estimation accuracy was evaluated over SNRs ranging from 60 dB to -40 dB in 20 dB increments. Wind noise in the absence of gusts was specifically considered, and experimental analysis confirmed that it could be approximated as locally Gaussian during these phases.

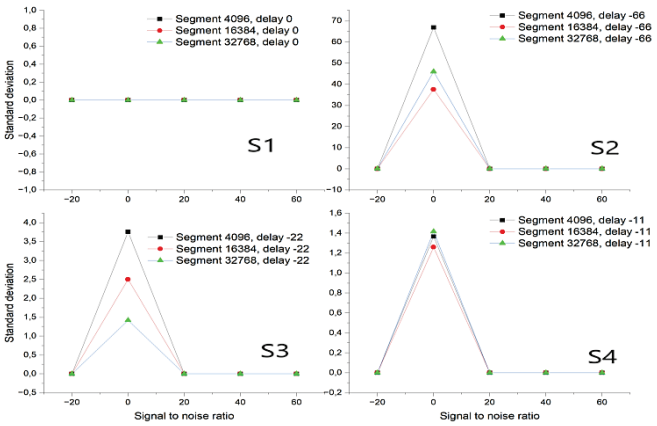

Fig. 3. Dependence of the standard deviation of the determined bearing on the SIR, with correlated interference

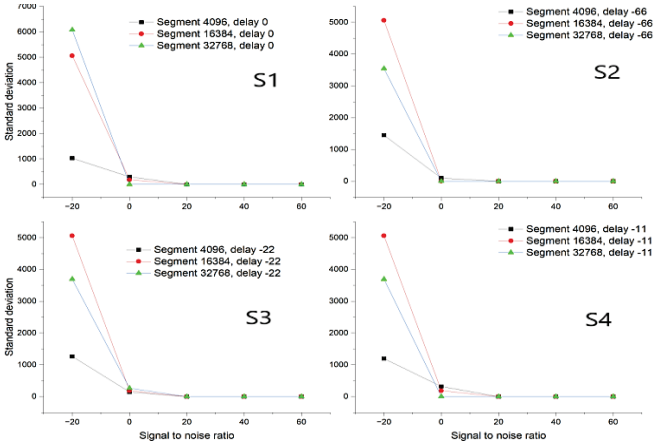

Fig. 4. Dependence of the standard deviation of the determined bearing on the SIR, with uncorrelated interference

Two representative results without corrector are shown in Figs. 3 and 4. For uncorrelated interference, the DFS showed consistent performance across all four scenarios, with standard deviation varying with SNR in the range of -20 dB to 20 dB, while for correlated interference, performance remained symmetrical.

C. Simulation Results with Corrector

In non-Gaussian interference scenarios, nonparametric detection methods have shown marked advantages over conventional linear parametric approaches. This study investigates nonparametric and semiparametric direction finding by converting the input signal into a binary quantized representation for both or only one microphones.

In particular, let the input signal at a microphone be denoted by $S_{1,2}(i)$. Its binary quantized version is given by

$$q(S_{1,2}(i)) = \begin{cases} +1 & \text{for } S_{1,2}(i) \geq 0 \\ -1 & \text{for } S_{1,2}(i) < 0 \end{cases}. \tag{9}$$

When both channels are quantized, say $S_1(i)$ and $S_2(i)$, the processing generates a signed correlator that implements a fully nonparametric detection scheme. The correlator output can be expressed as

$$C(k) = \frac{1}{N_0} \sum_{i=lN_0}^{(l+1)N_0} q(S_1(i)) q(S_2(i+k)). \tag{10}$$

In contrast, if only one channel (e.g., $S_1(i)$) is quantized while the other channel $S_2(i)$ remains in its analogy form, the method becomes semiparametric-combining a nonparametric transformation on one channel with a parametric model on the other. In this case, the signed analogy correlator is computed as:

$$C(k) = \frac{1}{N_0}\sum_{i=lN_0}^{(l+1)N_0} q(S_1(i))S_2(i+k). \qquad (10)$$

Simulation results for the performance evaluation after applying nonparametric and semiparametric corrector are shown in Figs. 5 and 6, respectively.

IV. Discussion

This study investigates the performance of acoustic DFS for UAV detection, focusing on the impact of SNR and environmental noise. Results show that bearing accuracy improves with higher SNR, with significant errors observed below 20 dB, emphasizing the need for better noise filtering. Correlated noise and gusty wind conditions further degrade accuracy, indicating the importance of sensor optimization for varying environmental factors.

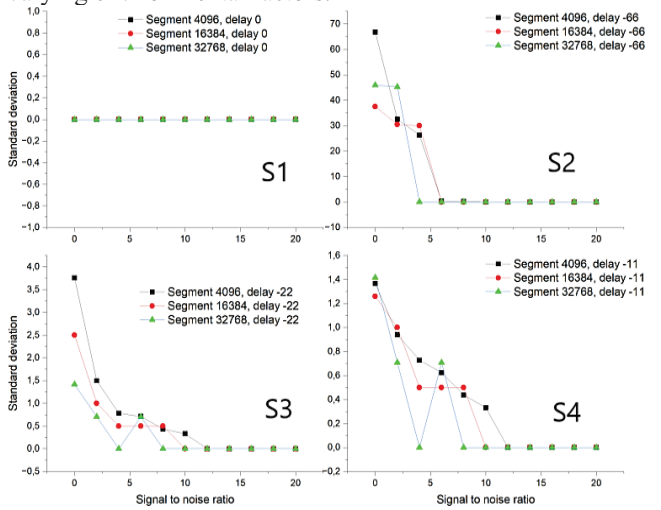

Fig. 5. Dependence of the standard deviation of the determined bearing on the SIR, with correlated interference, when using a nonparametric correlator

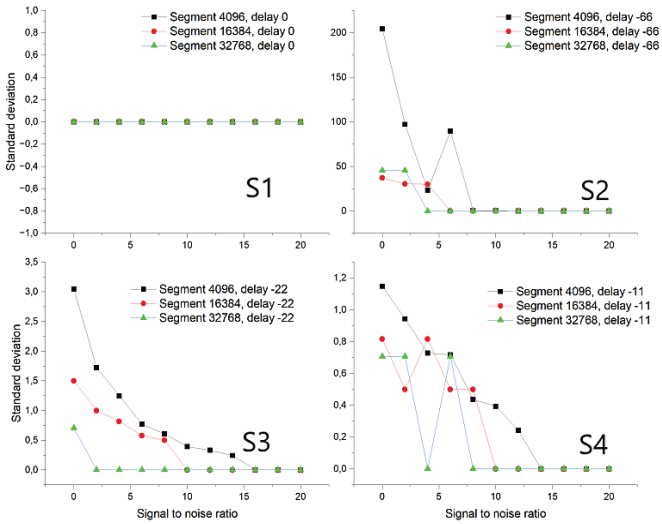

Fig. 6. Dependence of the standard deviation of the determined bearing on the SIR, with correlated interference, when using a semiparametric correlator

Nonparametric methods demonstrated superior performance, offering better efficiency in low-SNR scenarios. Increasing segment length (>4096 samples) enhanced noise immunity. To further improve system performance, future work should explore deep learning-based noise suppression and optimal sensor array configurations.

V. Conclusion

This study highlights the impact of SNR, noise type, and wind conditions on acoustic DFS performance for UAV detection. Nonparametric methods excel in low-SNR environments, and longer segment lengths improve noise immunity. Future work should focus on integrating advanced noise suppression and sensor optimization to further enhance system robustness in real-world scenarios.

Kharkiv, Ukraine
ORCID ID: 0000-0003-4478-3193

***Abstract*—In order for present-day electrical engineering programs to stay competitive and prepare graduates for successfully entering the workforce, they need to respond to changing market demands. This study aims to evaluate alignment between electrical engineering job postings and a number of study programs in STEM-focused higher education institutions in the EU. To achieve this, a thematic analysis of Industry 4.0 competencies in recent electrical engineering job postings is performed. Identified competency framework is applied to understand the supply-demand relationship between the study programs and the market. The findings reveal an over-supply in the core curricula, as well as strong supply of Industry 4.0-related knowledge. A subset of under-supplied but highly-demanded skills was also identified: self-management, communication, English language knowledge, collaboration, continuous learning, and knowledge transfer. The practical value of the study lies in providing practical insights for electrical engineering curriculum development and introducing a replicable data-driven method for benchmarking formal curricula against job market requirements.**

Keywords—Industry 4.0, electrical engineering education, higher education, curriculum development, labor market

I. Introduction

Industry 4.0 (I4), also referred to as the Fourth Industrial Revolution (IR4) has become a major transformational force for industrial environment of the 21st century. One of its defining characteristics, along with digitalization and reliance on modern technologies, is a surge in speed, scope, and systematic influence of change. This creates a challenging environment for all stakeholders—employers, workers, managers, regulators, consumers—pressing them to react and adapt accordingly [1-2].

The Industry 4.0 model is accompanied by heavy digitization of factory operations, introduction of inter-connected manufacturing components, and transformation of business processes to support flexible distributed operations [3]. An I4-ready "smart factory" incorporates a number of complex technologies, such as cyber-physical systems (CPS) and internet of things (IoT) [4] to transform its operations and achieve higher productivity, among other benefits. Other technologies often discussed in I4 manufacturing context are: additive manufacturing; big data and analytics; digital twins; artificial intelligence and machine learning (AI/ML); cloud computing; virtual and augmented reality (VR/AR); blockchain and distributed ledger technology (DLT); robotics; and cybersecurity [5].

Despite such a wide array of digital technologies shaping present-day manufacturing, the interconnected nature of Industry 4.0 with its emphasis on cross-hierarchy communication and increased stakeholder involvement [3] requires strong non-technical competencies for workers to succeed. Skill sets that were viewed mainly as requirements for knowledge workers are now an integral part of engineer's day-to-day work. A present-day engineer is expected to not only work with machines, but also design and integrate computerized systems, work with data, collaborate on projects, and take on leadership when necessary [6]. This applies not only to emerging, "I4-native", roles—existing jobs are transformed as well [7]. This puts developing relevant skills into perspective not only for graduates who are yet to enter the workforce, but employees already involved into the industry.

In this environment, engineering education is at the forefront as the work-readiness of future graduates depends on the content of today's study programs. Higher education institutions face changing requirements across the board: the content provided, the technologies used for teaching, and the need to provide students with experience interacting within interdisciplinary teams among other requirements [8]. This necessitates closer cross-sector collaboration and deriving insights in technology foresight from private sector and larger ecosystem actors [9].

As shown in a systematic review [10], Industry 4.0 has introduced significant skill gaps across a number of sectors. Recent research of engineering competencies confirms this and demonstrates lack of consensus on the unified competency framework for engineers to excel in I4 environment, leading to weaker alignment of study programs with current labor market demands [11-12]. This complicates curriculum modernization and creates tension between the need innovate and isomorphic pressures to make similar decisions [13].

Furthermore, despite the ongoing discourse, there exists limited evidence on Industry 4.0 skill gaps in electrical engineering (EE) higher education curricula, especially within the EU. The present study aims to address this by evaluating the alignment between Industry 4.0 competencies most frequently sought out in EU electrical engineering job postings and those taught in EU bachelor and master-level electrical engineering curricula. The choice of market as the benchmark for supplied competencies is grounded in Human Capital Theory, according to which education functions as an investment in productive capacity [14]. From this perspective, the labor market serves as a direct indicator of which competencies generate productive value. Thus, when employers consistently seek particular I4 skills across multiple job postings, it indicates that these competencies contribute to productivity and organizational success. By aligning their curricula with these market signals, higher education institutions can potentially increase the return on educational investment for both graduates and employers.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

The research contributes to curriculum development in electrical engineering education by providing practical insights for EU EE programs and introducing a replicable data-driven method for benchmarking formal curricula against market competency requirements.

II. Literature Review

The purpose of this literature review is to summarize current consensus regarding I4 competencies in broader and engineering contexts, and to identify main convergence domains. The review starts with evaluating existing literature to establish a foundation and understand the I4 competency landscape. The review continues with a summary of two major engineering accreditation guidelines: Accreditation Board for Engineering and Technology (ABET) criteria for accrediting engineering programs and European Accredited Engineer (EUR-ACE) Framework Standards and Guidelines. This allows contextualizing I4 competencies within the focus area of the study. Empirical and mixed-method studies are then reviewed to understand the convergence between theory and the industry environment. Based on the obtained results, a theoretical competency framework is synthesized.

Although the particular terminology differs, the majority of theoretical studies regarding I4 competencies [7], [15-16], as well as literature exploring engineering education in I4 context [11], [17] converge on the following high-level categories:

- Technical skills: computer programming, digital literacy and digital literacy 4.0 (communicating via Internet of Things or/and Internet of People [18]), data analysis, knowledge of specific tools etc. This category may also include industry-specific competencies, such as state of the art knowledge and skills, manufacturing, robotics, automation, etc.
- Personal/cognitive/methodological (i.e., applied individually as opposed to within a group) skills: flexibility, motivation to learn, creativity, problem-solving, research, self-directed and lifelong learning, etc.
- Interpersonal/Social skills: communication, communication competence 4.0 (human-human and human-machine communication, understanding of machine-machine communication [19]), intercultural skills, team work, etc.

The fourth category is domain-specific engineering competencies, which are referred to as Core skills within the context of this study. They comprise the foundation of electrical engineering curriculum and provide necessary prerequisites, including areas such as circuit design, electronics, electromagnetics, signal processing, control systems [20]. ABET criteria for EE curriculum further outlines other foundational disciplines, such as mathematics, sciences (biological, chemical, physical), probability and statistics, as well as broader engineering topics [21].

Next, let us review I4 skills included in formal engineering program accreditation criteria. ABET outlines the following relevant engineering program competencies: problem solving; effective communication; decision making; collaborative work; leadership; goal-setting and planning; analytical thinking; working with data; self-directed learning and knowledge acquisition [21]. EUR-ACE Framework Standards and Guidelines outline the following relevant competencies: problem solving; analytical thinking; research and critical evaluation of literature; safety regulations; data search and analysis; self-management; efficient communication; intercultural skills; self-directed learning; life-long learning; collaborative work [22]. Based on the results outlined in these studies, an engineering competency taxonomy was synthesized, as presented in Table I. This taxonomy serves as the theoretical foundation for the study.

Taxonomies developed in empirical and mixed-method studies [6], [23-26] largely align with the outlined categories and provide deeper insights into the context in which these competencies are applied and their influence. In a survey [6], both students and working professionals regarded personal skills (continuous learning, reliability) as highly important for I4 work. Authors also differentiated a fourth category of skills, digital (IT systems operation, data analysis), which gained more recognition from working professionals compared to students. A comparative analysis of I4 competencies for future managers and engineers in pharmaceutical and automotive sectors [24] showed a different facet of I4 skills—their transferability across sectors. The results of the study demonstrated a strong overlap in several competencies—efficiency orientation, research skills, analytical skills—while decision making, conflict solving, and problem solving all had high demand rates, albeit with less convergence.

In a study of the influence of I4 competencies on the employability of undergraduate and graduate-level business students [25], both technical and non-technical skills (encompassing personal and social categories) had a statistically significant impact on employability. The author also noted that students were aware of the changing job market and sought skills to improve their employability within the Industry 4.0 environment. Despite this alignment, some industry surveys show a gap between employers' expectations and prospective workers' skill sets. In a study of a group of

TABLE I. Engineering Competencies

Category	Skills
Cognitive skills	Problem solving Continuous learning Self-directed learning Critical thinking Adaptive thinking Cognitive flexibility Self-management Decision making Entrepreneurial mindset
Technical skills	Data visualization Software programming Digital literacy Ability to use AI tools
Interpersonal skills	Networking Leadership Conflict resolution Communication Collaborative work Intercultural skills Knowledge transfer
Core skills	Electronics Circuit design Power systems Control systems Electromagnetics Signal processing CAD and simulation software

[a] Source: Developed by author based on [7-8], [15-20], [22-27].

enterprises in Poland that claimed to implement Industry 4.0 concepts [26], the highest-reported roadblock to implementing I4 was lack of qualified employees (77% responses). Furthermore, the most demanded skills voiced by respondents were long-life learning (83%), social media skills (74%), technical and management skills (72%), and team work (72%).

As shown by this literature overview, there is a consensus on competencies relevant in the Industry 4.0 context. Employers, workers, and students understand the importance of I4 competencies, creating demand for acquiring them. However, possible gaps suggest misalignments between engineering study programs and industry needs. Furthermore, existing literature largely relies on methods like bibliometric analysis, systematic literature review, questionnaires and expert interviews to derive and categorize I4 competencies. There is a gap in approaches that rely on market data, such as job postings, particularly in the context of electrical engineering within the EU. For higher education institutions aiming to modernize their electrical engineering curricula, having up-to-date and relevant data allows making grounded, informed decisions.

Thus, the following research questions are formulated.

RQ1: To which extent do Electrical Engineering curricula at STEM-focused higher education institutions in the EU align with the competencies most frequently demanded in the current job market, as identified through a thematic analysis of job postings?

RQ2: Which competencies demonstrate the largest absolute and relative discrepancies between labor market demand and curricular coverage in these programs?

The outlined research questions provide a way to test the core assumptions of the Human Capital Theory in the example of Electrical Engineering in EU. That is, RQ1 examines the core assumption that formal education provides valuable skills, and RQ2 focuses on quantifying the expected return on investment (ROI) in human capital [14].

III. Methodology

The study employs a mixed-method approach, combining qualitative thematic analysis and quantitative code frequency analysis to identify trends and evaluate convergence between market-driven competencies and those identified within Electrical Engineering study programs. Thematic analysis method was selected for its flexibility and ability to systematically analyze qualitative, unstructured textual data. It allows for conceptual grouping of related terms and supports a meaningful synthesis across varied terminologies [27].

First, a thematic analysis of 73 publicly available job postings was performed. Samples were collected from LinkedIn platform in April-May of 2025 with the following parameters: search query “Electrical Engineer AND Industry 4.0”; entry level; located in European Economic Area (LinkedIn location identifier 91000002); not an “express of interest” listing. For each job offer, the requirements, skills, and responsibilities (where present) were collected.

The decision for selecting LinkedIn as the primary data source was driven by its popularity, high data availability, and frequent data updates. As authors in [28] note, online job platforms like LinkedIn can serve as valuable sources of labor market insights, highlighting advantages like timeliness, coverage, and high sample sizes. However, such platforms also have limitations, such as self-selection bias, the presence of spam content, and duplicate data. To address these limitations, several measures were implemented. First, duplicate entries were identified through manual review of job titles, company names, and posting dates, and removed from the dataset. Second, third-party recruiting agencies that posted job listings on behalf of other firms were identified and excluded to ensure direct employer representation and avoid inflated job availability metrics. Finally, to mitigate self-selection bias and capture temporal variations in job market activity, data collection was conducted over a period of several weeks.

The sample size of 73 job listings was driven by thematic richness and sufficient variation, as identified during the preliminary analysis of the dataset. Code saturation was achieved at 68 listings with remaining 15 serving as confirmatory data. These results are generally in line with [29], in which authors achieved 80% thematic saturation from 50 documents and 90% from 81 documents.

Codes during the thematic analysis of job listings were developed using mixed approach, incorporating deductive and inductive methods. The initial coding framework was developed based on findings from theoretical and empirical literature discussed in the previous section. During the iterative analysis process, novel categories and codes not covered by the existing framework were developed inductively through the examination of the data’s meaning and context. Both sets of codes were then integrated into a final framework. To ensure consistency of assigned codes, intra-coder reliability was evaluated by re-coding 15 randomly selected samples after one week. Percentage agreement measure was used, achieving over 90% agreement.

Next, a thematic analysis of 25 Electrical Engineering study programs was performed against the coding framework developed in the previous stage. Higher education institutions for the analysis were collected from the European Higher Education Sector Observatory (EHESO) database, using a data snapshot for 2022, with the following parameters: number of students enrolled at ISCED levels 5-7 in Engineering, Manufacturing, and Construction > 1000; STEM orientation ("share of students and graduates in science and technology" [30, p. 114]) > 0.6. The number of students enrolled in Engineering, Manufacturing, and Construction was used as a proxy for maturity of institution’s engineering faculty [31]. The threshold represented the top third of most STEM-dense institutions. This selection allowed focusing on institutions with mature, established engineering departments, which are more relevant within the context of the study. Then, bachelor and master-level Electrical Engineering programs, with openly available curriculum and module structures in English (regardless of whether the program is in English, a local language, or mixed), were selected, with no more than one program per institution. Where the program was available at both levels, the bachelor's level was preferred. Module information, learning outcomes, and competencies (where available) were collected. All elective or optional courses were included in the program's analysis for completeness. The 25 programs represented a complete dataset for the given parameters. For evaluating consistency, 5 randomly selected samples were re-coded after one week, achieving over 85% on percentage agreement.

To assess the convergence between demanded and supplied competencies, the following indicators are introduced: gap score Δ and supply-demand ratio *R*. Δ quantifies the absolute magnitude and direction of alignment or misalignment in percentage points. This is a direct and interpretable measure of the coverage gap that allows for ranking skills. *R*, on the other hand, captures the proportional relationship, allowing for the identification of significant disproportions or complete omissions ($R = 0$) when absolute differences may not provide the same degree of understanding. This choice of metrics has several advantages: transparent and reproducible, no statistical assumptions; allow both ranking and threshold-based classification; interpretable and enable visualizations that are easy to reason about.

For an *i-th* competence, the gap score Δ_i is calculated as follows:

$$\Delta_i = S_i - D_i \quad (1)$$

where S_i is the proportion of study programs providing the skill, D_i is the the proportion of job postings requiring it. $\Delta_i > 0$ indicates over-supply, $\Delta_i < 0$ indicates under-supply.

Supply-demand ratio R_i is obtained as follows:

$$R_i = S_i / D_i \quad (2)$$

Similarly, $R_i > 0$ indicated over-supply; $R_i < 0$ indicates under-supply.

IV. Results & Discussion

The following results were obtained from the thematic analysis of public Electrical Engineering job listings. The coding framework developed during the thematic analysis is presented in Table II.

Technical and interpersonal categories have the highest

TABLE II. Theme, Categories, and Codes

Theme	Categories	Codes
Skills and competencies required for electrical engineers in Industry 4.0 environment	Cognitive skills	Self-management Analytical thinking Problem-solving Continuous learning Self-directed learning Decision-making Entrepreneurship
	Interpersonal skills	Collaborative work Communication Knowledge transfer Networking Leadership Intercultural skills
	Technical skills	Technical writing Human-machine interaction Software programming Data analysis Project management Standards and regulations knowledge
	Industry 4.0	Artificial Intelligence (AI) and Machine Learning (ML) Knowledge of Industry 4.0 technologies and concepts Robotics Internet of Things (IoT) Embedded systems
	Language knowledge	English Work- or region-related language

density, with competencies in these areas constituting 22% of all job postings, followed closely by cognitive skills at 20%. Collaborative work has the highest demand; it was present in 79% of recorded job postings, followed by communication (73%), self-management (66%), and technical writing (56%). As for language requirements, knowledge of English language is required in 73% of jobs, another work-specific language—45%.

Regarding minimal educational prerequisites, a vocational degree is required in 10% of postings, a bachelor's degree in 59%, a master's degree in 5%, and a PhD in 3%. Additionally, 11% of collected jobs mention professional certifications. Prior work experience is required in 62% of jobs.

RQ1: *To which extent do Electrical Engineering curricula at STEM-focused higher education institutions in the EU align with the competencies most frequently demanded in the current job market, as identified through a thematic analysis of job postings?*

To gain an overall understanding of the alignment between demanded and supplied skills, let us conduct a basic statistical analysis of the described metrics. As shown in Table III, the overall alignment is moderate. The 1.2 difference between the minimum and maximum values of Δ suggests existence of outliers on both ends. Furthermore, the 2.3 standard deviation in *R* suggests a relatively high level of inconsistency in taught competencies despite balanced central alignment.

The initial assessment of competency supply and demand, as presented in Fig. 1, reveals several observations about the nature of their relationship. First, there is a moderate over-supply subset at ~0-20% demand. On the other hand, several high-impact competencies at > 60% demand have lower supply. Mid-tier skills at 25-60% demand is generally over-supplied with a spike at ~35% demand.

RQ2: *Which competencies demonstrate the largest absolute and relative discrepancies between labor market demand and curricular coverage in these programs?*

The analysis of skills provided in the study programs reveals the following findings: categories with the highest density are technical (30%), cognitive (20%), and Industry 4.0 (20%) skills. The most prevalent skill is software programming, present in 92% of the study programs collected, followed by analytical thinking (88%) and embedded systems (80%). Interpersonal and language categories each constitute 10% of all skills. English is taught in 44% of programs, while a second language is taught in 36%.

The overall ranking of competencies by appearance in job advertisements is as follows (ascending): 1—cybersecurity; 2—decision-making; 3—AI and ML; 4—IoT; 5—robotics; 6—intercultural skills; 7—project management; 8—leadership; 9—data analysis; 10—self-directed learning; 11—continuous learning; 12—knowledge transfer; 13—software programming; 14—Industry 4.0 general knowledge; 15—problem-solving; 16—work-specific language; 17—analytical thinking; 18—human-machine interaction; 19—technical writing; 20—embedded systems knowledge; 21—self-management; 22—communication skills; 23—English language knowledge; 24—collaborative work.

As seen in Fig. 2, a number of competencies are oversupplied. This can be explained by institutions aiming to provide a broader set of skills to prepare graduates for a wider

TABLE III. METRIC SUMMARY

Measure	Δ	R
Min	-0.62	0.00
Max	0.58	10.22
Mean	0.05	2
Median	0.04	1.08
σ	0.29	2.3

range of possible jobs. Let us take a closer look at a subset of high-demand low-supply competencies identified previously. They are: self-management (Δ = -0.62, R = 0.06), sought-out in 66% of job descriptions while taught only in one program; communication (Δ = -0.25, R = 0.66); English proficiency (Δ = -0.29, R = 0.61); and collaborative work (Δ = -0.31, R = 0.6). Continuous learning (Δ = -0.22, R = 0) and knowledge transfer (Δ = -0.18, R = 0.18) are also under-supplied.

For the Industry 4.0 category, on average, supply exceeds demand, with a mean R value of 3 and a mean Δ value of 0.22. The only skills with slightly lower supply are general knowledge of Industry 4.0 concepts (Δ = -0.05, R = 0.87), usually presented through the lens of a particular study program (e.g., smart grids).

Several competencies identified as under-supplied in formal curricula, namely self-management, collaborative work, continuous learning, and knowledge transfer, are frequently mentioned as hidden curriculum components [32]. These may be implicitly developed through activities such as lab work and group assignments or obtained as part of the general culture of engineering education, even if they are not explicitly stated in learning outcomes or course syllabi. However, because this study analyzes only publicly documented curriculum elements, it is not possible to evaluate the extent to which the hidden curriculum compensates for formal gaps.

Among examples where such skills are included in the explicit curriculum is Eindhoven University of Technology, which requires a minimum of one multidisciplinary Challenge-Based Learning (CBL) project per semester with "personal & professional development" as one of its objectives. Another notable example is Karlsruhe University of Applied Sciences. Its Electrical Engineering program includes a Journal Club module where students are expected to learn critical thinking, effective communication methods, presentation skills, and knowledge conveyance, among others.

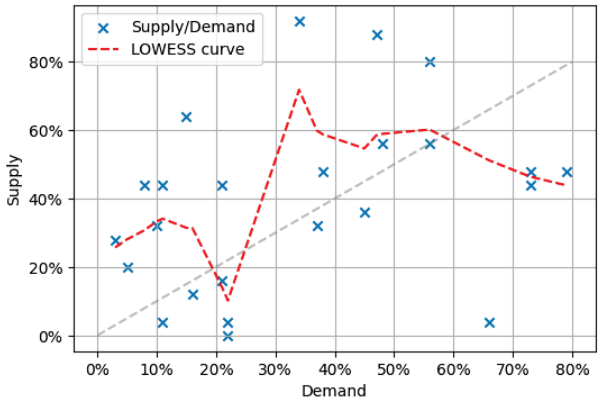

Fig. 1. Competency supply and demand.

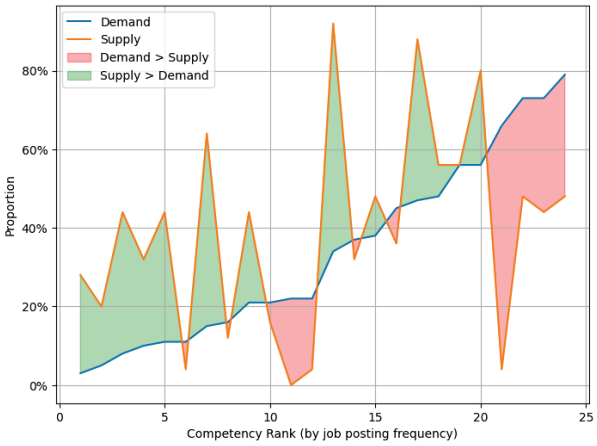

Fig. 2. Competency supply-demand gap; each numbered position represents a competency, ranked by frequency of appearance in job advertisements (1 = least frequently demanded). Data available in [33].

V. CONCLUSIONS

The study aimed to evaluate the alignment between Industry 4.0 competencies most frequently demanded in EU electrical engineering job postings and those formally taught in EU Electrical Engineering curricula. To achieve this, a mixed-method analysis was performed, starting with a thematic analysis of recent electrical engineering job postings, and followed by a thematic analysis of bachelor and master-level EE programs in STEM-focused higher education institutions in the EU.

Results reveal a moderate-to-high over-supply of competencies in the core curricula, with distinct subsets of highly demanded but under-supplied skills: self-management, communication, English language proficiency, collaborative work, continuous learning, and knowledge transfer. Skills in the Industry 4.0 category have a strong supply, with the only under-supplied skill being general knowledge of Industry 4.0 concepts.

The obtained findings confirm the core assumptions of the Human Capital Theory. That is, educational investment provides individuals with in-demand skills, which, in turn, enable future benefits in both the monetary (workers with more in-demand skills have higher competitiveness on the labor market), and non-monetary (better working conditions, increased performance, etc.) forms [14]. However, the subset of over-supplied competencies may require a deeper investigation. Higher education institutions that over-invest in certain competencies that are less widely demanded risk providing students with a less balanced skillset, which, in turn, decreases the overall ROI as these investments could be used to address more in-demand competencies.

The methodology applied in this study can be replicated for internal assessment of a given study program or for competitive benchmarking within a country or region. This data-driven approach allows for obtaining results within a short time frame using limited, publicly available data and provides a solid foundation for reasoning regarding the modernization needs of a study program's curriculum.

The study has two main limitations. First, the thematic analysis of curricula was limited to formal curriculum documents publicly available in English. This limitation reduced the number of study programs available for analysis and may have omitted competencies addressed through

hidden curricula or informal instruction. Second, foundational EE competencies were deliberately excluded to focus on Industry 4.0-specific skills. This aligns with the purpose of the study; however, including core skills may provide a deeper understanding of the alignment between study programs and market demands.

Future studies in this direction may focus on the following: including job-specific requirements (PCB design, CAD software, etc.) to gain a broader understanding of the alignment between supplied skills and employer expectations; evaluating core curriculum and elective modules separately; assessing the density of provided competencies (e.g., in ECTS credits).

***Abstract*—The paper shows the ways of complex modernization of power units of the power plant in the city of Kharkov, Ukraine. The aim of the study is to develop conceptual solutions for the use of a gas turbine cycle and solid oxide fuel cells (SOFCs) as a superstructure for the modernization of powerful steam turbine plants to increase their energy efficiency. As an example, a 60 MW gas turbine considered as a superstructure over a 100 MW steam turbine. In addition to the combined cycle, the integration into the combined plant of a SOFCs modular plant with a total electrical output of 20 MW was also considered. The SOFCs modular plant consists of 40 tubular solid oxide fuel cells with a unit electrical output of 500 kW and with an internal reforming. A new method was developed that makes it possible to carry out a correct comparative thermodynamic analysis of combined cycles of power plants. The method is based on the use of a modified criterion of the structural complexity of the power plant modernization with a graphical apparatus for the optimization of thermodynamic cycles. By this method it was determined that the schemes of the combined cycle with SOFCs have a higher efficiency with acceptable complexity of modernization in comparison with the combined schemes of the steam-gas plant of different configurations. In addition, the method makes it possible to take into account the size of the area required for the placement of additional equipment during modernization.**

Keywords—combined cycle, energy efficiency, gas turbine, modernization, solid oxide fuel cell, steam turbine

I. Introduction

The problem of increasing energy production is especially relevant today in Ukraine. At the same time, priority should be given to the modernization of the electrical component of the combined heat and power plant (CHPP) in comparison with the rate of increase in heat supply.

Natural gas remains the main fuel for Ukraine power plants today, which can be used more efficiently in combined cycle power plants (CCPPs), in which the part of the fuel is introduced into the gas circuit. CCPP is a combined unit consisting of a gas turbine and a steam turbine. At a high heat supply temperature in the gas turbine and a heat removal temperature in the steam turbine condenser equal to almost the ambient temperature, the temperature ratio of hot and cold heat sources in the steam-gas cycle and its efficiency increases significantly. The efficiency of the steam turbine cycle is 30–35% [1] and the efficiency of modern gas turbines is 37–41%, while the efficiency of the combined cycle power plant is 42–60% [2]-[5].

Currently, much attention is paid to the design of combined power plants based on gas turbines and fuel cells. Basically, solid oxide fuel cells (SOFCs) are used for this. SOFCs are based on solid materials with ionic conductivity. The operating temperature of SOFCs is in the range of 1173...1273 K [6]. The efficiency of fuel cells is not limited by Carnot's law. Therefore, combined power plants based on fuel cells can be increased to 75% [7]. The fuel cells known today can produce from 0.3 MW to 30 MW of electrical energy [8]. In modern SOFCs the reforming of hydrocarbon fuel into hydrogen occurs directly in the fuel cell [9], [10].

Today a topic task is not only the creation of new power plants, but also the reconstruction of existing power units of thermal power plants through the introduction of a gas turbine cycle and solid oxide fuel cells.

II. Literature Analysis and Problem Statement

There are many scientific papers which discuss how to improve the efficiency of the combined cycle. So, Rao et al. [11] consider the question of a combination of Brayton's and Rankin's cycles, which provides an overall cycle efficiency of up to 60%.

Voloshchuk et al. [12] give examples of studies based on mathematical modeling using MathCAD Calculation Server technology for some operation cycles of a gas-steam turbine power plant. The internal efficiency of the combined cycle can reach 66%. This is achieved by using methods of thermodynamic analysis and optimization of combined cycles [12]-[15]. Also optimization methods are widely used to improve energy parameters, as well as economic and environmental indicators [16]-[21].

Aminov et al. [22] and Godoy et al. [23] give examples of combined cycle power plants developed in the world. It is shown that in order to ensure operation reliability, high thermal efficiency, low specific costs and operating costs, power gas turbines are currently designed according to the simplest cycle at the maximum achievable gas temperature. At the same time, the pressure increase degree values are chosen close to optimal ones, which correspond to the maximum efficiency for combined cycle power plants using the heat of the turbine exhaust gases.

To date, on the basis of the GTE-60 gas turbine of the State Enterprise "Zorya-MASHPROEKT" a couple of combined cycle gas turbines of various capacities have been developed. Combined cycle gas turbines CCGT-85 with a capacity of 85 MW and CCGT-170 with a capacity of 168 MW have an efficiency factor of at least 52% [4], [24].

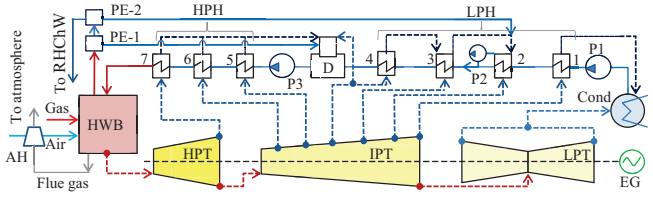
Modern papers are also devoted to the development of hybrid power plants consisting of solid oxide fuel cells and a

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

gas turbine or combined cycle gas turbine [25], [26]. There are also schemes for combining SOFCs with an internal combustion engine [27] and an air turbine [28]. New effective methods to analyze strength and dynamics characteristics of gas turbine units are developed in [29], [30].

Thus, basically all research is devoted to the development of new highly efficient combined power plants. This definitely makes it possible to achieve a high energy efficiency of the power units with minimal capital costs. However, there are certain requirements for the modernization of CHPP power units, which do not always allow the implementation of recommendations that are obtained by thermodynamic analysis and thermoeconomic optimization of combined cycles. This is usually due to technical, design, economic and CHPP architecture limitations. Therefore, there is a need to develop methods for finding rational solutions for the modernization of existing CHPP power units.

III. Goal and Research Objectives



The goal of the study is to develop ways to introduce the gas turbine cycle and solid oxide fuel cell technology as a superstructure over existing powerful steam turbine plants. The research objectives are as follows:

- design and thermodynamic justification of various combined schemes for the modernization of the existing 100 MW CHPP power unit;
- development of a method for finding rational solutions for the modernization of existing CHPP power units;
- comparative thermodynamic analysis of energy efficiency and structural complexity of various combined schemes for the existing 100 MW CHPP power unit modernization.

IV. Thermodynamic Analysis of Various Combined Schemes for the Modernization of the 100 MW CHPP Power Unit

An analysis of the state of the power units operated at the CHPPs of Ukraine showed that power units with a lower exhausted resource include power units with a capacity of 100 MW and 250 MW. Thus, the Kharkiv CHPP-5 power units can be chosen as an example for modernization. This is especially true in connection with the military situation today.

As an example, the reconstruction of a power unit with a T-100/120-130 steam turbine [31] is considered. The basic thermal scheme of a power unit with a T-100/120-130 steam turbine is shown in Fig. 1. The regeneration system consists of four low pressure heaters (LPH), a deaerator (D) and three high pressure heaters (HPH). Connection type is cascade (without the use of drainage pumps).

HWB – hot water boiler; HPT, IPT, LPT – high, intermediate and low pressure turbine; AH – air heater; Cond – condenser; EG – electric generator; P – pump

Fig. 1. The basic thermal scheme of a power unit with the T-100/120-130 steam turbine.

The scheme uses a drum-type boiler with continuous purging. To reduce heat losses, the purge water is directed to a two-stage continuous purge expander, and then to the regenerative heater of chemical water treatment (RHChW), and then it is discharged into the sewer. From the first stage purge expander (PE-1) steam is directed to the deaerator, and from the second stage purge expander (PE-2) steam is directed to the LPH-2.

The factory data of the T-100/120-130 steam turbine are as follows: power output is $N_e = 100$ MW; live steam pressure is $P_0 = 127.5$ bar; live steam temperature is $T_0 = 555$ °C; calculated values of the internal relative efficiency by compartments are $\eta_{oi}^{HPT} = 95\%$, $\eta_{oi}^{IPT} = 95\%$, $\eta_{oi}^{LPT} = 97\%$; electromechanical efficiency is $\eta_{em} = 98\%$; transport efficiency is $\eta_{tr} = 98\%$; surface type heaters efficiency is $\eta_H = 98\%$. These data were obtained at a nominal steam mass flow rate $G = 115$ kg/s. In all calculations, it was assumed that the steam loss in the deaerator is 2% of G.

Modern CHPPs operate, as a rule, on turbines with steam extraction, the main advantage of which is the ability to work according to an independent schedule of electrical and thermal loads. In condensing mode, the turbine operates for about 2000–2500 hours per year. The electrical efficiency of a steam turbine operating in the heating mode is about 30%, and in the condensing mode it is about 37%.

Considering the foregoing, in this paper we propose to carry out and justify the way to increase the efficiency of CHPP by creating combined power plants, including a gas turbine as a superstructure, as well as innovative environmentally SOFCs.

It is proposed to choose a GTE-60 gas turbine for the modernization of the CHPP power unit, which is based on the standard Brayton cycle. The compression ratio in the gas turbine compressor is 18. To achieve a turbine inlet temperature of 1295 °C, natural gas (methane) is burned. Methane consumption during combustion is 3 kg/s. Then the combustion products expand in the turbine to a pressure of 1.1 atm. The temperature of the flue gases is 517 °C. Adiabatic efficiency (75.2% and 92.0% for compressor and turbine respectively) and combustion efficiency (98%) are calculated from experimental data [4], [24]. The gas turbine efficiency is 37% [32].

It is also proposed to use a modular plant with a total electrical output of 20 MW of 40 tubular solid oxide fuel cells with internal reforming. The temperature at the inlet of the tubular SOFCs is 800 °C, the temperature at the outlet of the tubular SOFCs is 1000 °C, and the efficiency of the SOFCs for generating electricity is 55% [33].

In this paper various variants for the possible combination of a steam turbine with a gas turbine and also with a gas turbine in combination with fuel cells are discussed. The thermodynamic parameters of various combined schemes are determined using a lumped approach to the analysis of each of its elements [34], [35].

A typical scheme of parallel connection of a gas turbine to a steam turbine is shown in Fig. 2. This scheme uses a waste heat boiler consisting of a number of heat exchangers. It is also called a Heat Recovery Steam Generator (HRSG). It creates steam for the steam turbine by passing hot exhaust gases from the gas turbine through banks of heat exchanger tubes.

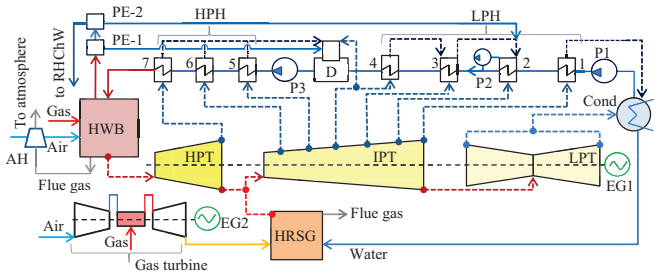


Fig. 2. The scheme of parallel connection of the GTE-60 gas turbine to the IPT of the T-100/120-130 steam turbine (scheme A).

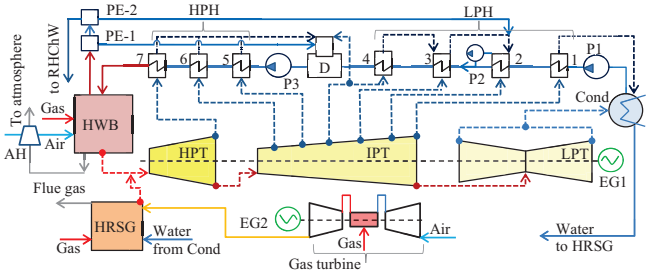
The HRSG can use natural circulation or use forced circulation by means of pumps. As the hot exhaust gases past the heat exchanger tubes in which hot water circulates, heat is absorbed causing the creation of steam in the tubes. The tubes are arranged in sections, or modules, each serving a different function in the production of dry superheated steam.

The temperature of flue gases from GTE-60 is only 517 °C. This does not allow heating the steam in HRSG to the required temperature of the live steam supplied to the high-pressure turbine. Therefore, the additional steam flow from the HRSG is supplied to the intermediate-pressure turbine.

Such a connection allows increasing the electrical efficiency of the power plant up to 42% in the condensing mode. With this connection of the gas turbine, the scheme of the steam turbine remains practically unchanged. Therefore, capital investments during modernization will be spent mainly on a GTE-60 gas turbine with HRSG.

When GTE-60 is connected by parallel with afterburning fuel in HRSG, steam is heated to a live steam temperature of 555 °C and has a pressure of 12.8 MPa. This makes it possible to direct live steam from the HRSG to the high pressure turbine (Fig. 3). Such a connection makes it possible to increase the electrical efficiency of the power plant up to 44.75% in the condensing mode.

Another parallel connection variant with SOFCs modular plant is shown in Fig. 4. Here, the steam is heated to the required temperature of live steam due to the heat of the gases leaving the modular plant of solid oxide fuel cells with additional gas afterburning in the HRSG. The total electrical output of the SOFCs modular plant is 20 MW. The flue gas temperature in this case is 740 °C, which makes it possible to superheat the steam to the required temperature. Taking into account the utilization of the heat of the flue gases coming from the gas turbine and SOFCs, the thermal capacity of the HRSG for heating, water evaporation and steam superheating is 133.12 MW. The electrical efficiency of such a power plant will be 49.4% in the condensing mode.



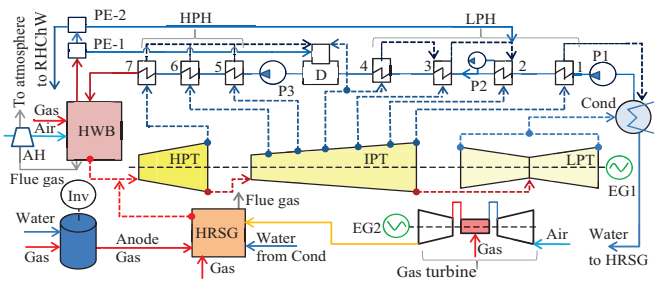


Fig. 3. The scheme of parallel connection of the GTE-60 gas turbine to the HPT of the T-100/120-130 steam turbine with fuel afterburning in the HRSG (scheme B).

Inv – SOFCs DC/AC inverter; Anode Gas – waste gas at the SOFCs outlet

Fig. 4. The scheme of parallel connection of the GTE-60 gas turbine to the HPT of the T-100/120-130 with fuel afterburning in the HRSG and SOFCs (scheme C).

A simple scheme for connecting gas turbine to the steam turbine was considered (Fig. 5). Here, flue gases coming from the gas turbine go instead of heated air to the HWB. This can be done because the flue gases leaving the gas turbine contain 15–17.5% O_2. A stoichiometric calculation shows that the flow rate of air required for the combustion of natural gas, for example, from the Kegichiv gas field is 162 kg/s for the steam turbine operation. Taking into account the decrease in the oxygen level during its burnout in the GTE-60 combustion chamber from 21% to 17.5%, it becomes necessary to increase its flow rate to 175.5 kg/s. This is practically equal to the flow rate of 173.4 kg/s of exhaust gases leaving the GTE-60 gas turbine. The heat supplied to the HWB with flue gases of GTE-60, taking into account the fact that they are cooled to 300 °C, is 44 MW. In this case, the electrical efficiency of the combined plant will be 41% in the condensing mode.

The thermal power of the flue gases leaving the HWB when they are cooled from a temperature of 300 °C to 120 °C is 36 MW and can be used to heat network water or replace low-pressure regeneration. Thus, replacement of regeneration from 4 to 7 extractions (see Fig. 1) leads to an increase in electrical efficiency in the condensing mode up to 42.6% (scheme E).

The inclusion of a SOFCs modular plant with a total electrical output of 20 MW in a simple scheme of a combined plant will increase the electrical efficiency up to 46% in the condensing mode. Such an increase in efficiency is achieved due to the complete replacement of regeneration with the utilization of the heat of waste gases from fuel cells and flue gases of the HWB (replacement of HPH and LPH with a HRSG) (Fig. 6).

The absolute increase in the electrical efficiency of various schemes η_{ei} compared to the electrical efficiency of the basic scheme of a power unit with the T-100/120-130 steam turbine η_{ebas} is shows in Fig. 7. The index i denotes various schemes.

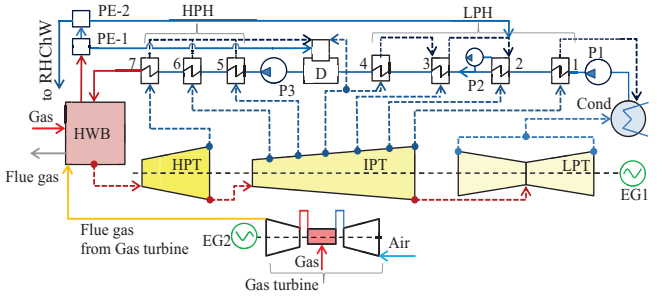

Fig. 5. A simple scheme for connecting the GTE-60 gas turbine to the T-100/120-130 steam turbine (scheme D).

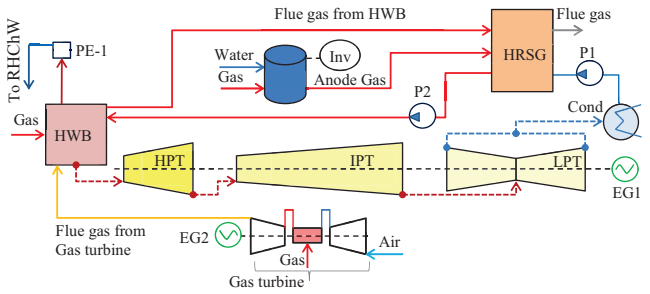

Fig. 6. A simple scheme for connecting the GTE-60 gas turbine to the T-100/120-130 steam turbine with SOFCs modular plant and replacement of regeneration (scheme F).

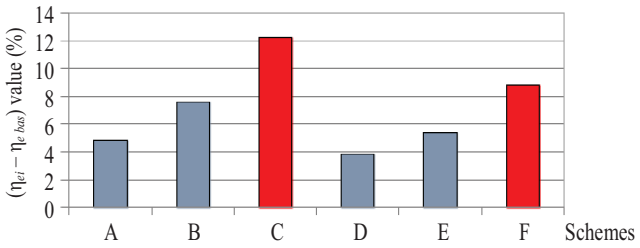

Fig. 7. Absolute increase in the electrical efficiency of schemes A-F compared to the basic scheme of a power unit with the T-100/120-130 steam turbine.

The greatest increase in electrical efficiency by 12.2% compared to the basic scheme of the CHPP power unit is achieved in scheme C of the CCPP with the SOFCs modular plant.

V. Choice of the Rational Scheme for the Modernization of the 100 MW CHPP Power Unit

It is advisable using the methodology of system-structural analysis to search for a rational structure of a technological combined schemes and configurations of a thermodynamic cycle that provide high energy efficiency under given conditions [34]. An important element of this analysis is the estimate of the level of structural complexity of the technological scheme. When creating new combined plants, the estimate of the schemes structural complexity level can be carried out using the criterion D_c proposed by Taubman:

$$D_c = D_i' (2\bar{m} + \bar{p}). \quad (1)$$

The criterion D_c takes into account the total number of interactions of the heat engineering system with the environment $\bar{p}$ (for example, heat removal from the condenser), the total number of technological connections between the system elements $\bar{m}$ and the total complexity of all elements D_i'. If the compared schemes are the similar in complexity of the main equipment, then the D_i' value is taken equal to 1 [36].

This method makes it possible to carry out a comparative thermodynamic analysis of power plant cycles using a deterministic criterion of constructive complexity and a graphical apparatus of C-curves. Thus, already at the stage of initial design of the system, it is possible to obtain as a universal method for determining schemes that are optimal in terms of energy efficiency. The introduction of the scheme complexity criterion into the pre-design analysis makes it possible to facilitate of choose for a rational scheme and makes the analysis results visual and informative.

Schemes A-F (Figs. 2-6) differ in structural complexity. One of the parameters for a correct comparison of schemes is the equality of the steam flow rate at the HPT inlet.

The dependence of the $1/\eta_e$ value on the scheme complexity criterion D_c is shown in Fig. 8, a. The $1/\eta e$ value is introduced for convenience. As can be seen from Fig. 8, a, only one C-curve can be drawn through the points Basic-E-F-C. According to the theory of graphical optimization [37], it is necessary to select the arc of choice that limits the schemes with the minimum value of $D_{c\,min}$ and with the minimum value of $1/\eta_{e\,min}$. Thus, in this case, the arc of choice is the F-C curve. Basic scheme and schemes A, B, D, E are not included in the arc of choice, since they have more complexity than scheme F and less efficiency than scheme C.

Thus, the analysis of schemes according to the theory of C-curves makes it possible to reduce the number of the schemes variants. It can be interpreted as follows. If we consider the tasks of creating a new combined plant, then the choice should be made between the two schemes F and C with SOFCs. For the final choice of the rational variant out of the two selected, it is necessary to carry out the thermoeconomic and environmental analysis [37]-[39].

If we consider this task from the point of view of the modernization of an existing CHPP power unit, one should take into account not only the structural complexity of the scheme, but the complexity of modernization by replacing one structural connection with another.

We proposed the following criterion for the structural complexity of modernization

$$\Delta D_c = D_i' (2 (\bar{m}_{ad} + \bar{m}_{rem}) + \bar{p}_{ad} + \bar{p}_{rem}), \quad (2)$$

where "ad" and "rem" are the subscripts of added and removed elements, respectively.

As can be seen from the Fig. 8, b, the largest ΔD_c value has the scheme F, which has the lowest D_c value. This is explained by the fact that when modernizing the steam turbine, it is necessary to replace the regenerative heat exchangers with a new heat recovery steam generator. Fig. 8, b shows the C-curve obtained by connecting the points D-B-C-F. The arc of choice D-B-C is limited by ΔD_c min and $1/\eta_{e\,min}$. It can be seen that schemes A, E and F are not included in the arc of choice. Scheme D has the least complexity of modernization, and scheme C has the highest efficiency with acceptable complexity of modernization. Thus, combined cycle scheme C with SOFCs (Fig. 4), which is included in both arcs of choice, can be considered as a variant for modernization of an existing CHPP power unit.

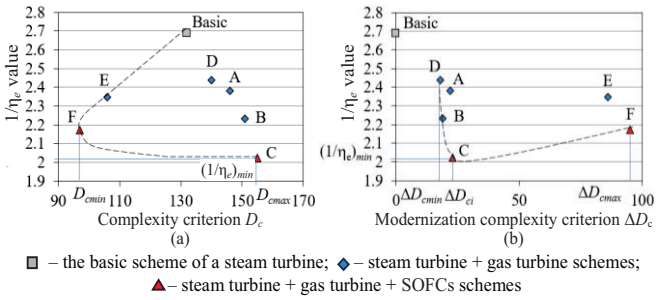

Fig. 8. Dependence of the $1/\eta_e$ value on the scheme complexity criterion D_c (a) and on the scheme modernization complexity criterion ΔD_c (b).

However, such an analysis does not allow making the final choice of a rational scheme. During modernization, an important factor is the possibility of installing additional equipment, taking into account the architecture of the CHPP. There should be enough space for modernization. Therefore, it is necessary to estimate what additional area will be required for the modernization of each scheme located on the arc of choice D-B-C. GTE-60 dimensions are as follows: length is 5.6 m, width is 3.3 m, and height is 3.5 m. The dimensions of one SOFC with an electrical output of 500 kW are: diameter is 2 m, height is 2.8 m. The HRSG for a gas turbine with a capacity of 60 MW has approximate dimensions of 26100×10230×12100 mm and a weight of about 260 tons.

The results of calculating the area A required for the placement of additional equipment, excluding pipelines, for each scheme B, C and D are shown in Table 1. Also, these data are shown in Fig. 9, a.

As can be seen from Table 1 and Fig. 9, a, the most efficient scheme C with SOFCs requires the largest area for the placement of additional equipment during modernization.

Therefore, if during modernization there is a condition for limiting the area for additional equipment placement, then for a correct analysis of the schemes, it is necessary to build the dependence of the ratio of the scheme electrical efficiency to its modernization complexity criterion $\eta_e/\Delta D_c$ on the ratio of the additional equipment placement area to scheme modernization complexity criterion $A/\Delta D_c$ (Fig. 9, b).

As a result of graphical analysis, if there is not enough space for additional equipment, from all schemes it is necessary to choose the combined cycle scheme B (Fig. 3), which is included in the arc of choose according to the scheme modernization complexity criterion ΔD_c (Fig. 8, b), has the highest ratio $\eta_e/\Delta D_c$ at an acceptable $A/\Delta D_c$ value (Fig. 9, b).

VI. Results Discussion

A method has been developed that makes it possible to carry out a comparative thermodynamic analysis of combined schemes of power plants. This method is based on the use of the proposed modified criterion of the structural complexity of the plant modernization in combination with a graphic representation. Fig. 8 compare the curves $1/\eta_e = f(D_c)$ and $1/\eta_e = f(\Delta D_c)$ using the classic complexity criterion D_c and the modified modernization complexity criterion ΔD_c. The first analysis can be applied when creating a new combined plant, and the second one when modernizing an existing one.

The combined scheme C with SOFCs during creation has the greatest complexity D_c and highest efficiency. But if we consider modernization, then the complexity of this scheme is significantly reduced from $D_c = 155$ to $\Delta D_c = 23$. Thus, combined cycle scheme C with SOFCs can be considered as a variant for modernization of an existing CHPP power unit.

The area required for the placement of additional equipment during modernization was also taken into account. Scheme C has the largest placement area. Thus, as a result of graphical analysis, combined cycle scheme B without SOFCs can be considered as a variant for modernization of an existing CHPP power unit in the conditions of limited space for additional equipment placement.

For a more correct choice of the scheme, it is necessary to supplement the method with thermoeconomic and ecological-exergy analysis [37]-[39].

TABLE I. Additional Equipment, its Quantity, Area for its Placement and the Increase in the Electrical Efficiency of Schemes B, C and D Compared to the Basic One

Scheme	ΔD_c value	GTE-60 (60 MW)	HRSG	SOFCs module (20 MW)	Area A, m^2	$(\eta_{ei} - \eta_{ebas})$ value, %
		Quantity; area for element placement				
B (Fig. 3)	19	1; 18.48 m^2	1; 267 m^2	No	285.48	7.6
C (Fig. 4)	23	1; 18.48 m^2	1; 298 m^2	1; 114 m^2	430.48	12.2
D (Fig. 5)	18	1; 18.48 m^2	No	No	18.48	3.8

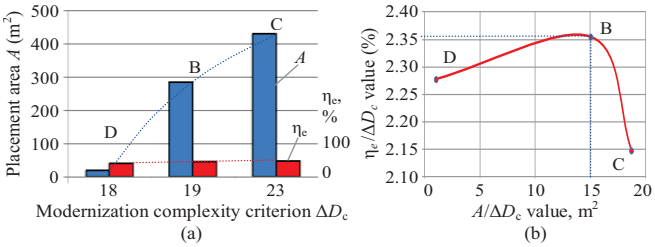

Fig. 9. The A, η_e values (a) and the dependence of the $\eta_e/\Delta D_c$ ratio on the $A/\Delta D_c$ ratio (b) for schemes B, C and D.

VII. Conclusions

Various combined plant schemes for the modernization of the existing 100 MW CHPP power unit were proposed. These schemes include a gas turbine and a SOFCs modular plant. For each scheme, a thermodynamic calculation of the cycle was carried out and the parameters and efficiency of the scheme were determined.

A method was developed for finding rational solutions for the modernization of existing CHPP power units based on the use of a modified criterion of the structural complexity of the power plant modernization.

A comparative thermodynamic analysis of energy efficiency and structural complexity of various combined schemes for the modernization of the existing 100 MW CHPP power unit was carried out. It was determined that combined cycle schemes with SOFCs have a higher efficiency with an acceptable complexity of modernization. A rational combined cycle scheme without SOFCs was also chosen taking into account the limitation of the area required for the placement of additional equipment during modernization.

***Abstract*—This study focuses on the analysis and prioritization of enemy targets to support effective mission planning involving strike drone swarms. The goal is to improve the validity of selecting relevant targets for their effective engagement using available UAVs. Various scenarios for conducting military missions using a swarm of drones and a set of possible targets for engagement are considered. A list of criteria for assessing target priorities is proposed in order to identify a subset of high-priority targets. A graphical diagram of an extended hierarchy of prioritization criteria and possible targets is developed. A software tool using the Analytical Hierarchy Process has been developed to prioritize targets for strike drone missions.**

Keywords—strike UAVs, drone swarms, mission planning, target prioritization, criteria, Analytical Hierarchy Process.

I. INTRODUCTION

Unmanned aerial vehicles (UAVs) for various purposes have been widely used in the Russo-Ukrainian War. Special attention should be paid to the use of strike UAVs for suppressing enemy fire and engaging various types of targets. Groups of UAVs control a specific territory with the aim of damaging or completely destroying detected targets [1].

The relevance of this research area is driven by the growing use of UAVs in military operations in the form of drone groups, both homogeneous and heterogeneous (combinations of reconnaissance and strike drones). In this paper, the term "swarm" refers to a group of drones ranging from several units to several dozen, acting jointly within a mission to strike a target, but capable of employing different launch tactics and route formation strategies (waves, maneuvering, swarm splitting). Such swarms are often controlled by a single operator or by means of artificial intelligence.

They are capable of comprehensively performing reconnaissance tasks in a specific sector of military operations, suppression of enemy electronic warfare systems (EW), and simultaneously destroying their air defense systems (ADS) and other objects in accordance with the operational plan of the military unit's command.

II. ANALYSIS OF PUBLICATIONS

Currently, there are many publications on improving the effectiveness of UAVs, including swarm UAVs. Issues related to the use of various types of equipment for destroying enemy targets are being considered. The use of military UAV technology by armed forces is characterized by the use of numerous and more functional drones that can operate in large numbers.

There are practical developments in the planning of military missions for UAV swarms (the Mission Control module of the DELTA military system) [2]. At the same time, issues such as the distribution of areas of responsibility, crew route planning, and real-time coordination of tasks for UAVs are already being addressed.

An important step in planning military drone missions is selecting priority enemy targets for fire. This task must be solved based on a number of criteria using modern decision-making methods and technologies. A manual focused on the application of NATO standards for planning enemy fire missions using artillery indicates the need to select relevant targets and even provides several criteria for their evaluation [3]. However, these criteria are generalised, qualitative in nature, and do not reflect the specifics of the use of strike drones.

The article [4] defined the components of the process of military engagement of the enemy using the "target tree" method based on functional characteristics, with greater emphasis on the processes of obtaining information about the situation, assessing the situation, and distributing forces and means of engagement between tasks.

The article [5] identified the key factors that shaped the target setting tasks. These include technological developments, organizational structures and processes, and competition between types of troops for limited resources. In addition, target setting formation is influenced by intelligence data on the nature of the enemy and assumptions based on experience, doctrine, or strategic theory. The target setting process is characterized by a tendency toward increasing the accuracy of ammunition and the ability to strike specific targets while constantly reducing response times and increasing distances from the target.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

There are researches devoted to the stage that comes after target setting – the detection of specified targets and the control of drone swarm movement. For example, monograph [6] discusses the calculation of waypoints in advance or the generation of new waypoints during a mission. Methods have been proposed for detecting targets based on UAV aerial photographs for small targets, dense locations, sparse distribution, and complex backgrounds using artificial intelligence, namely, feature extraction using asymmetric convolution [7].

With regard to the criteria for assessing the relevance of targets, given their priority for engagement by a swarm of UAVs, there are currently insufficient publications. Thus, in article [8], solution is presented for the problem of determining the location of objects by drones with minimum cost in a two-dimensional terrain. The number of drones and total energy consumption are the two cost indicators considered. The problem is solved mathematically by forming integer linear and mixed nonlinear optimization models. Article [9] considers four main criteria for selecting targets. However, the essence and influence of these criteria on the superiority of the solution aren't disclosed; they are evaluated subjectively, on a linguistic scale.

Regarding modern methods for assessing the importance of objects, special attention should be paid to the Analytical Hierarchy Process (AHP), which is widely used in decision-making and allows the decision problem to be structured as a hierarchy of goals, criteria and alternatives, with a focus on expert subjective judgments. This method can be combined with other decision-making approaches and has several modifications. Fuzzy logic methods are effective when uncertainty and vagueness in the input data need to be taken into account. For example, fuzzy TOPSIS (FTOPSIS) is a modification used to determine priorities based on indicators with fuzzy values [10]. Unlike the AHP method, neural networks demonstrate high performance on large data volumes and can autonomously learn complex relationships, although they lack transparency in explaining the decisions [11]. The AHP method is more suitable for tasks with a clearly defined structure and the involvement of experts.

Thus, in the task of prioritizing targets for strike UAVs, the issue of analyzing and forming a set of criteria for the selection task remains unresolved, and no formalized procedure for their evaluation has been proposed. The aim of this study is to improve the validity of the selection of relevant targets for their effective engagement by available UAVs.

III. Materials and Methods

A. *Basic definitions and provisions of the decision-making task for target engagement*

Let us consider the main provisions regarding the task of decision-making on engagement enemy targets using a swarm of UAVs.

Military operations are planned based on the collection of intelligence information. Based on the results of identifying potential targets, a decision is made on whether a specific object requires action to destroy it.

The military operations planning headquarters prepares decision-making information that answers the following questions [12]:

- What targets should be attacked?
- When and where targets can be found?
- What means should be used to determine the exact location of targets?
- How accurately the location of a target must be determined in order to attack it?
- What priorities exist for intelligence, tasks, and the distribution of forces and resources?
- What requirements are important for target detection?
- When, where, how, and in what order targets should be attacked?
- What are the indicators of mission performance and effectiveness?
- What means should be used to attack targets (number/type of UAVs, their armament) in order to achieve the desired effects?
- How quickly and in what format this information should be obtained and processed?

There are two levels of UAV use by military units [13]. The general task of using weapons is to use forces and means across the entire zone in the interests of the battle as a whole, carried out to the full depth of the enemy's battle order. It's done through fire raids and other actions. The direct task of using weapons is to use forces and stuff in the area of responsibility of general military formations to carry out specific tactical tasks in a limited area (in the direction of their actions). Based on reconnaissance information, the task of targeting is decided – the process of selecting, prioritizing (importance) of targets and coordinating the appropriate impact on them, taking into account operational requirements and capabilities [13]. This task is part of operational planning and is based on a cycle consisting of the following main phases:

a) Based on the concept, task, and instructions from the command, determine the Named Area of Interest and Target Area of Interest.

b) Determining targets and their priority, based on which a High Payoff Target List (HPTL) is developed.

c) Analyzing the possibilities for target engagement; implementing additional measures that may affect the distribution of UAV resources.

During planning, lists are formed: No-Strike List; Restricted Target List; HPTL.

The current assessment of the military capabilities of available engagement means helps to conduct a realistic analysis of efforts to determine the effectiveness of engagement, review plans for the use of engagement means based on observed results, and change the priorities of subsequent targets.

The High Value Targets list is compiled based on the relative importance of the target to the enemy's operations. High Value Targets include capabilities, functions, or systems that are critical to the enemy in the context of military. High Payoff Targets are those nodes among high-importance enemy targets whose elimination renders the node non-functional. Keep in mind that too many high-

priority targets will spread out the effort to gather info, locate the target, and destroy it.

According to [13], the following general criteria are used to analyze the significance of targets and their verbal assessment: criticality; accessibility; recouperability; vulnerability; effect; recognizability.

The targeting working group reduces, modifies, and prioritizes high-importance targets, ensuring that high-priority targets support the command's concept of battle.

Waves of strike drones allow for a massive attack on enemy targets to inflict maximum damage. For effective military missions, the engagement of targets must be taken into account [14]:

- Consists in the complete destruction of selected actual enemy targets.
- Inflicting damage that prevents the enemy from continuing to conduct successful military operations on the battlefield.
- The need to force the enemy to switch from active offensive operations to defense or retreat.
- The objectives of a military operation aimed at intercepting the military initiative.

It should be noted that prioritizing goals makes it possible to solve two interrelated tasks. Thus, at the strategic planning stage, after identifying high-opportunity goals, it is necessary to analyze the combat potential of existing UAVs, taking into account their tactical and technical characteristics, which will enable the effective performance of engagement tasks as part of a drone swarm. If it turns out that the available resources are not capable of performing the task due to their characteristics, or there are not enough drones of a certain type in military units, appropriate measures should be planned:

- Implement projects to modify UAVs to ensure certain characteristics.
- Implement projects to increase the production of certain types of drones.
- Make decisions to improve the logistical support of military units.

The opposite task is operational and tactical planning of the use of existing types and numbers of drones to form a swarm. When selecting high-priority targets, the technical characteristics of the drones should also be taken into account, and targets that can be struck with maximum effectiveness should be selected.

B. The method of evaluating targets by particular parameters in the analytic hierarchy process

In general terms, the task of making decisions on determining high-priority goals boils down to the following list of actions:

- Determining the enemy's engagement strategy.
- Selecting a set of targets (of various types) for implementing the specified strategy (high-importance targets).
- Determining the weighting coefficients of the criteria for selecting the type of target.
- Evaluating target types based on a set of criteria.
- If there are several targets of the same type, conducting an additional analysis of options based on a subset of relevant criteria.
- Forming a list of high-priority targets, taking into account their parameters (based on quantitative and qualitative characteristics).

Thus, we have a hierarchy of objects for determining their priorities: at the first level – evaluation criteria, at the second level – types of goals, at the third level – specific goal options with their parameters.

Let us consider the AHP method for multi-criteria evaluation of objects from a set of options [15].

Each x_i object (target) receives an expert assessment G_{mi} for the selected P_m parameter. Then, using special rules for comparing two objects, square matrices of A_m paired comparisons are formed for each m parameter for all n objects. This matrix has the properties of inverse symmetry, i.e. $a_{ij}=1$, at $i=j$, where i is the row number, j is the column number and $a_{ij}=1/a_{ji}$.

To form a matrix of paired comparisons for the selected parameter, the values of the expert assessment are analyzed based on the scale of relative importance, ranging from equal importance (1) to absolute superiority (9), with intermediate values and reciprocal numbers used for finer judgments.

To determine the priority value of objects for each parameter, two operations are performed:

1) Normalization of the matrix – all values in each column are divided by the sum of that column, which makes it possible to obtain relative indicators.

2) Calculation of weight coefficients – for each object, the average value of the row in the normalized matrix is determined. These average values form the priority vector for the given parameter.

The same operations are repeated for each parameter. As a result, a matrix of the importance of objects across all parameters is formed. Then, the relative importance of the parameters themselves is taken into account, which makes it possible to obtain a generalized priority vector. This vector reflects which objects (targets) have the highest importance, considering all the criteria.

IV. ANALYSIS OF TARGET OPTIONS FOR ENGAGEMENT BY A SWARM OF DRONES AND CRITERIA FOR THEIR EVALUATION

The main functions of military UAVs are [16]: reconnaissance; combat engagement of various targets; interception and engagement of air targets.

It should be noted that an effective option is to form a combined-purpose swarm, where one or more drones are used for reconnaissance among the main body of strike drones. In this case, the task of selecting high-priority targets can be supplemented in real time with relevant information from the battlefield or the engagement area.

The types of reconnaissance or engagement targets are as follows [17]:

- Permanent locations of military units and areas of troop concentration (reserves), command posts.
- Airfields, naval bases, training grounds, and training centers.
- Bases, depots for weapons and military equipment, fuel and lubricants, material and technical resources.
- Enterprises of the defense-industrial complex and oil refining industry.
- Important infrastructure and communications facilities (railway junctions, bridges, and overpasses).

After identifying potential targets, the task is to determine the optimal route. For this purpose, the following route "cost" criteria are used:

1) Distance factor – the sum of the route lengths.

2) Resource factor – the total amount of resources spent by UAVs to achieve the targets.

3) Intersection factor – the number of intersections of the route with others.

4) Time factor – the time it takes for all UAVs to reach their targets.

For strike targets, the time factor directly affects the effectiveness of the mission, which is most often measured by the probability of hitting the target. Thus, in [18], a study is presented on the basis of which it can be argued that to hit 20 targets with a group of 3 strike UAVs with a probability higher than 0.5, the flight time should be no more than 14 minutes.

For large targets (infrastructure objects) or dynamic targets (military equipment during combat or movement), the following factors are important: the number of strikes required – depends on the amount of ammunition (in turn, the amount depends on the number of drones in the swarm and the maximum weight of ammunition on each of them); target exposure time, disappearance time for impact.

For spatial targets, the probability of engagement depends on the required engagement zone radius and the speed of the strike UAV [18].

Thus, the first thing to consider when assessing target priorities is the military mission scenario. Let us form a set of possible scenarios with the identification of factors that will influence the selection of targets and the criteria for their assessment (see Table I).

Based on the analysis of factors affecting the success of hitting a target with a swarm of drones, the following criteria can be used to assess their priorities:

- Relevance of enemy targets for engagement – impact on the mission, military importance of the target (strategic/operational/tactical priority).
- Economic or strategic value of the object.
- Urgency of engagement.
- Probability of successful engagement.
- Required combat potential (resistance to engagement, area of impact).
- Time required to achieve (or range).
- Level of threat to drones (presence of ADS or EW).
- Target accessibility.
- Depth of the target in enemy military formations or rear.
- Mobility, maneuverability of the target.
- Reliability of information about the target.

TABLE I. POTENTIAL PRIORITY OBJECTIVES FOR DIFFERENT TYPES OF MILITARY MISSION STRATEGIES

Types of targets	**Types of strategies**					
	Counterattack	***Defense of positions***	***Isolation of the combat area***	***Conditions of limited resources***	***Engagement of ADS***	***Operation in urban areas***
Locations of military units		+				
Command post	+	+				
ADS	+				+	
Airfields, naval bases		+				
Training grounds and centers				+		
Depots for military equipment and material resources				+		
Defense industry enterprises				+		
Infrastructure and communications facilities			+			

The first three criteria (relevance, value, urgency) are factors determined by the command at the strategic (or operational) level. They are the ones that influence the classification of the targets under consideration as high-priority targets. In addition, some criteria are correlated. For example, all other criteria (range, combat potential, threat level, etc.) influence the probability of successful engagement. More about these and other criteria when planning UAV missions in the authors' work [14].

V. SOFTWARE IMPLEMENTATION OF THE GOAL PRIORITIZATION METHOD IN DRONE MISSION PLANNING

A software system for prioritizing criteria and objectives based on information about planned strategies for military missions of strike drones has been proposed. The developed system can be used by a targeting group to prioritize targets based on expert assessment and using certain objective information about command plans, tactical and technical characteristics, and the number of drones available for military missions. Fig. 1 shows an example of a graphical diagram of an extended hierarchy for prioritizing targets for engagement by a swarm of strike drones. The first level is the target, the second is the level of strategies or scenarios (see Table II), the third level is the level of criteria for evaluating targets. The fourth level is the level of alternatives. An implemented example of evaluating such targets with elements: "Command post"; "ADS"; "Ammunition depot"; "Military convoy in motion"; "EW"; "Defense enterprise" etc. The system allows to form a hierarchy of decision-making tasks of any complexity and content. Fig. 2 shows the stage of hierarchy formation in the form of strategies and criteria. Fig. 3 shows an example of prioritizing criteria (on a scale from 1 to 9) to compare their importance in implementing the "Counterattack" scenario.

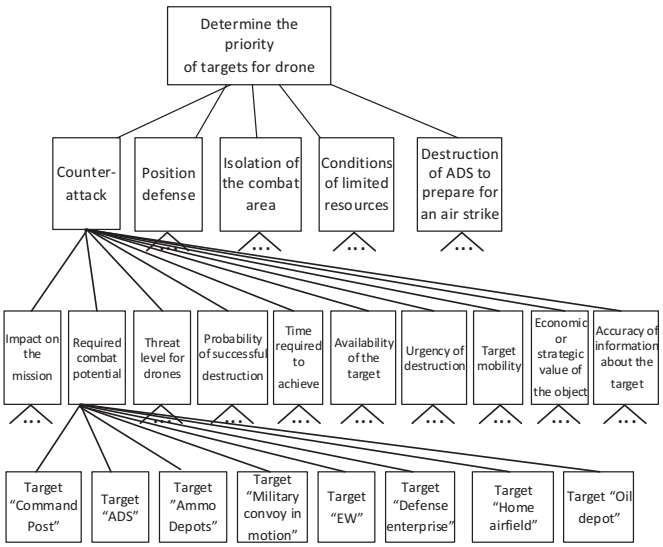

Fig. 1. Graphical diagram of the extended hierarchy

Fig. 4 shows the results of pairwise comparisons of scenarios, criteria, and alternatives. The obtained values of importance vectors for scenarios and criteria for each of them are presented in Table II. Fig. 5 shows a diagram of the priority vector of criteria for the "Counterattack" scenario. Fig. 6 shows a diagram of the priority vector of enemy targets for engagement in the "Counterattack" scenario.

The system we propose is integrated into a strategic and tactical UAV mission planning framework (Fig. 7). It enables the simulation of complex combat scenarios (Fig. 8), target selection and prioritization, prediction of losses, automatic route generation for drone groups, wave-based attacks, and the assessment of the expected mission effectiveness.

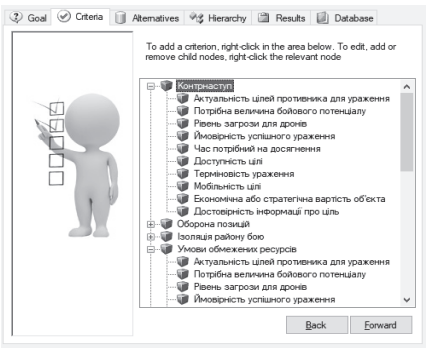

Fig. 2. Forming a hierarchy to prioritize UAVs targets

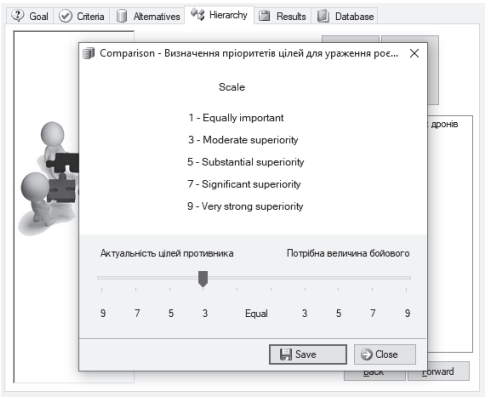

Fig. 3. Comparison of the criteria importance according to the "Counterattack" scenario

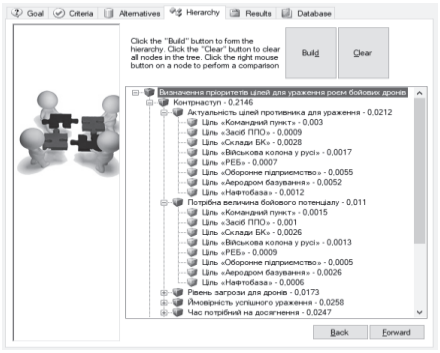

Fig. 4. Results of pairwise comparisons of scenarios, criteria, and alternatives

TABLE II. VECTORS OF CRITERIA PRIORITIES BY SCENARIOS

Criteria	**Scenarios**				
	Counter-attack	***Defense of positions***	***Isolation of the combat area***	***Limited resources***	***Engagement of ADS for preparation of an air strike***
Scenario priorities	0.246	0.1219	0.1219	0.3198	0.1293
Relevance of enemy targets for engagement	0.0212	0.0087	0.0083	0.0138	0.0107
Combat potential	0.011	0.0131	0.0106	0.0425	0.0109
Level of threat	0.0173	0.0133	0.0151	0.0417	0.0117
Probability of successful engagement	0.0258	0.0142	0.0187	0.0414	0.0142
Time to achieve	0.0247	0.0106	0.0138	0.0359	0.0142
Target availability	0.0201	0.0212	0.0106	0.0295	0.0099
Engagement urgency	0.036	0.0121	0.0171	0.0464	0.0209
Target mobility	0.013	0.0146	0.0074	0.0168	0.0122
Economic or strategic value of the object	0.0353	0.0072	0.0123	0.0356	0.0098
Reliability of information about the target	0.0103	0.0069	0.0079	0.0161	0.0148

CONCLUSIONS

A review of the available literature indicates that research on the specific task of selecting relevant targets for engagement by a swarm of drones is still very limited. To the best of our knowledge, no direct publications on this problem have been identified. Comparable studies are found mainly in the context of artillery operations, particularly drawing on NATO experience. The main provisions regarding the task of making decisions on the engagement of enemy targets using a swarm of UAVs are considered. The main phases of operational planning for the engagement of enemy targets are provided. The task of determining a set of high-importance and high-priority targets is formulated. The possibility of using the results of target prioritization at the strategic level for planning UAV modernization projects and at the tactical level for the use of available means of target engagement is considered. The stages of the general task of decision-making on the determination of high-priority targets are listed, which made it possible to justify the use of the AHP method. The main result of the article is an analysis of options for targets for drone swarm attacks and criteria for their evaluation. A set of strategies for performing military missions using drone swarms has been developed. In accordance with this set, types of targets and criteria for their evaluation have been determined. For the target prioritization process, developed software is proposed that automates pairwise comparison of alternatives and calculates their relative priorities.

Further research will focus on improving route generation algorithms and simulation modeling of goal achievement with an assessment of the probability of completing a military mission.

***Abstract*—the paper presents a modification of the basic method used to transfer multi-model augmented reality objects. The analysis of existing developments has proven the relevance of this task. A client application with augmented reality technology has been created using a combination of Angular, Node.js, Ar.js tools together with A-Frame. The loading speed of a 3D object using the basic and modified methods has been investigated. The limits of application of the modified method have been determined.**

Keywords—web, augmented reality, AR, Angular, multi-modeling.

I. Introduction

Over the past three decades, the development of Internet technologies has progressed from the static and one-way model of Web 1.0 to the interactive, personalized, and intelligence-oriented Web 4.0, demonstrating significant advances in the field of web technologies [1]. One of the modern innovative and interactive technologies that is actively being integrated into client-side applications is Augmented Reality (AR).

The development of web applications using augmented reality technology opens up new opportunities for shaping a novel user experience. AR web applications operate directly within web browsers, eliminating the need for additional software installation. They can be launched on most widely used mobile devices, including tablets and smartphones [2].

Examples of AR applications include websites that apply photo filters, feature interactive games, conduct virtual tourist tours, enable virtual try-on or product visualization, and provide various skills training. At the same time, the number of studies related to augmented reality is steadily increasing. It can be assumed that in the near future, AR-enabled websites will be able to provide users with a daily extension of reality [3].

The active implementation and dynamic development of client applications with support for augmented reality technology is due to a number of key factors, including:

- widespread daily use of websites in various spheres of human activity;
- the growth of mobile device users;
- increasing the availability and accuracy of geolocation services;
- expanding the coverage of high-speed mobile networks.

Collectively, these prerequisites foster an increasing demand for the development of AR-based web applications (WebAR), positioning this domain as a pertinent and timely area of modern web engineering. The fundamental building blocks of such applications are augmented reality libraries, which provide the essential AR functionality.

II. Literature Review and Problem Statement

Augmented reality enables the integration of digital content, such as images, audio, or text into the user's real-world environment, creating a rich and interactive experience. As it evolves, augmented reality is transforming into an effective tool for enhancing cognitive capabilities and supporting managerial decision-making across various domains, including mechanical engineering, healthcare, urban infrastructure, business, and tourism [4]. Within the web environment, two primary types of AR systems are distinguished based on their functional characteristics [5, 6].

The first type is marker-based. These systems utilize visual markers as triggers for overlaying digital content onto the physical world. Marker-based web AR systems typically consist of three key components: the marker itself, the AR application, and the web page. This technology is widely applied in museums and exhibitions, as well as in the fields of commerce and healthcare [5, 7].

The second type of augmented reality system is based on geolocation and does not require pre-defined markers. This technology leverages GPS, digital compasses, or other sensors to determine the user's coordinates, upon which AR objects are overlaid onto the physical environment or replace its elements. Such systems demand greater computational resources and more complex processing, which introduces certain technical challenges. Compared to marker-based AR, they are generally less accurate and stable. Markerless WebAR solutions are most commonly applied in gaming, e-commerce, and healthcare domains [5, 7].

Mobile devices, particularly smartphones and tablets, are most frequently used to interact with augmented reality web applications, as they are widely available and easily accessible. Additionally, headsets, smart glasses, and Head-Up Display (HUD) projection systems are employed to project images onto transparent screens in front of the user's eyes. A promising direction of development is the creation of AR contact lenses, which are currently in the research and prototyping stage [7].

In the development of software utilizing augmented reality, access to high-quality computer vision libraries and tools for object recognition and tracking is essential. These AR libraries form the foundation for the accurate and efficient operation of such applications. To fully implement AR functionality, two key types of libraries are required.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

The first type is responsible for determining the spatial positioning of a 3D object. In markerless augmented reality, this is achieved using geolocation data. In marker-based AR, object positioning is established through visual marker recognition. Libraries that serve this purpose include ARToolKit.js, AR.js, MindAR, as well as commercial platforms such as Vuforia and ZapWorks [8].

The second type of libraries used in WebAR development specializes in graphics and is responsible for constructing scenes to visualize 3D objects. These libraries provide tools for creating, configuring, and animating three-dimensional scenes within an augmented reality environment. The most widely used graphics libraries include WebGL, Babylon.js, Three.js, and A-Frame.

The most common approach in the development of AR web applications involves combining tracking libraries with graphics libraries. The results of an analysis of these two types of AR libraries [9, 10] are presented in a comparative table (Table 1), which outlines combinations of libraries used for computing the spatial positioning of 3D objects and rendering their graphical representation.

TABLE I. COMPARISON OF COMBINATIONS OF AR LIBRARIES

Combination of libraries	Main purpose	Advantages	Disadvantages	Difficulty level
A-Frame + AR.js	Fast and efficient development of AR web applications	Ease of integration, high speed of implementation, minimal amount of code, ease of use	Limited flexibility and functionality compared to more complex solutions	Low
Three.js + ARToolKit.js	Advanced development with complex scenarios	Great flexibility and extended functionality, integration with other libraries	Higher volume of code, complexity of use	High
MindAR + Three.js	Using machine learning in AR	The possibility of integration with TensorFlow, support for complex tokens, advanced possibilities for interactivity	Less popularity and support compared to AR.js, more difficult to learn	High
Vuforia або ZapWorks + Three.js	Comprehensive development of AR applications with support for web interfaces	Platforms for the development of mobile and web AR applications, a powerful API for integration	Main focus on mobile applications, possible limitations when working with web applications	Medium

Special attention is required for applications that utilize multi-model augmented reality objects. During their development, it is necessary to apply solutions designed to handle a relatively large total volume of models being loaded.

The authors of [11] present the development of a markerless AR website intended for veterinary student education. The site enables the viewing of an AR object without requiring any custom site logic, and therefore uses HTML as the markup language. Augmented reality functionality is implemented using the <model-viewer> web component rather than a full AR library. All interaction logic, such as user interaction with the 3D object, is handled entirely by this component. There is no dedicated server; instead, a remote host is used to store and deliver the 3D models.

The solution presented in [12] enables training in the use of medical therapeutic devices through AR/VR technologies. The developed web system consists of a Node.js-based server, a Socket.IO module, and the Three.js library. The server stores and synchronizes the state of the medical equipment. The Socket.IO module adds functionality that allows the 3D model of the equipment to respond to changes made on a mobile phone. Three.js is used to render the 3D object on the phone screen.

In [13, 14], neural network methods were employed to develop recommendation systems for art compositions within augmented reality systems.

In [15], the Alpaca framework was developed to allow third-party web developers to easily and efficiently integrate AR components into their own web applications. Alpaca consists of a client-side module implemented using HTML5, JavaScript, and Three.js-based AR rendering tools, and a server-side module built using the Python aiohttp library.

The outcome of the work presented in [16] is a web-based tool for generating resumes for job seekers, featuring augmented reality elements such as QR codes and AR markers. Augmented reality functionality in the application is implemented using a combination of two libraries: AR.js and A-Frame.

Despite significant progress in the development of client-side augmented reality applications [11–16], the reviewed studies do not focus on applications based on multi-model augmented reality. When the loading time of AR modules exceeds an acceptable threshold, freezes or delays in rendering may occur, which are perceived negatively by users.

III. THE AIM AND OBJECTIVES OF THE STUDY

The aim of our work is reducing the loading time of multi-model AR objects by developing a modified method for loading AR modules.

To achieve this goal, the following tasks were set:

- develop a client application with augmented reality technology;
- modify the method of transmitting multi-model augmented reality objects in order to reduce the overall transmission time;
- conduct a comparative study of the basic and modified methods of transmitting multi-model augmented reality objects.

IV. DEVELOPMENT OF A CLIENT APPLICATION WITH AUGMENTED REALITY TECHNOLOGY

This section presents a web application with augmented reality elements, with the client side implemented using the Angular web framework. Owing to its comprehensive functionality and strong community support, Angular is a suitable choice for developing medium-complexity applications. Due to the simplicity of integration, rapid development speed, minimal codebase, and ease of use, augmented reality functionality is implemented through the integration of the AR.js and A-Frame libraries. These

libraries enable the use of both marker-based and markerless AR within web environments.

A server-side component is also required for the complete implementation of the application. Given that Angular is based on TypeScript – a language closely related to JavaScript, JavaScript was chosen for the server-side logic. Node.js was selected as the server platform due to its popularity and ease of use, while the Express.js framework was employed to accelerate development and simplify configuration.

The application development process consisted of several key stages, each of which played an important role in the overall architecture of the project (Fig. 1).

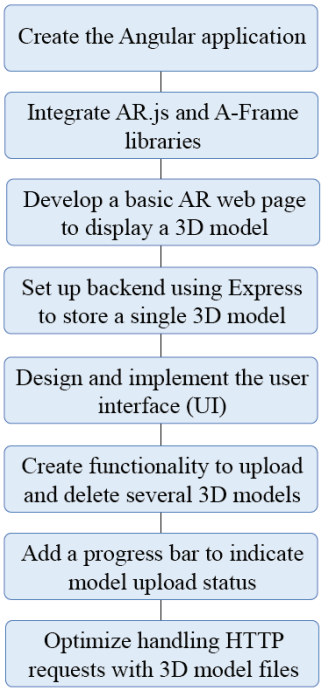

Fig. 1. Development scheme of a client-side application with augmented reality elements, divided into stages

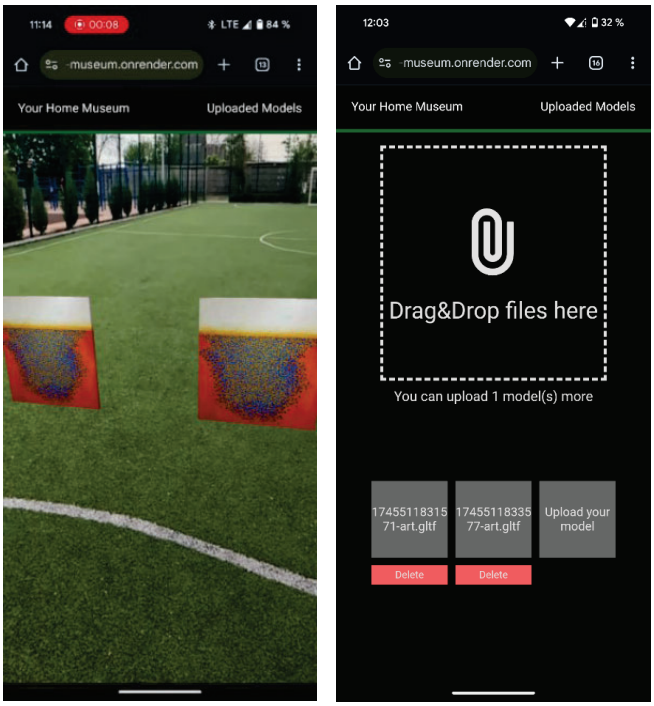
The first three stages were aimed at developing a basic working version of the application with minimal functionality. The initial version of the application consisted of a web page displaying a single AR object.



At the fourth stage, the server-side component was integrated to enable the storage and transmitting of the AR object.

Subsequent stages focused on extending the application's functionality, including support for multiple AR objects, mechanisms for uploading and deleting objects, and improving the user interface for enhanced usability.

The final stage, carried out after the planned functionality had been implemented, involved modifying the handling of HTTP requests related to model transmission. A detailed description of this process is provided in the following section.

As a result of the development process, a client-side web application with support for augmented reality elements was implemented, along with a server-side part responsible for storing 3D AR object files. A markerless approach using geolocation data was employed as the augmented reality technology. The outcome is presented in Fig. 2a.

The input data for the client application are .gltf files that contain the description of 3D models. Users are able to upload their own files from a local device. The upload functionality is implemented on a dedicated page of the application – **Uploaded Models** (Fig. 2b).

a b

Fig. 2. Results of client application development: a – display of augmented reality elements; b – page of loaded augmented reality objects

The output of the client application is a real-time 3D visualization of models in an augmented reality environment, rendered through the device's camera (Fig. 2a). In addition, a dynamic list of uploaded models is generated and automatically updated whenever objects are added or removed (Fig. 2b).

The result of the work is an interactive client-side application with a user interface that supports the uploading, management, and visualization of 3D objects in an augmented reality environment, accompanied by a server-side component responsible for model storage and processing user requests.

V. Method of Transmission of Multi-Model Augmented Reality Objects

The processing of HTTP requests associated with the transmitting of AR models involves several key stages. This process spans both the client-side and server-side components and includes a sequence of typical operations. Let us introduce a set of variables that denote the execution time of each individual stage:

- t_1 – HTTP request initiation time;
- t_2 – authentication and authorization time (if necessary);
- t_3 – time to process the request and send a response;

- t_4 – time to load and parse the model;
- t_5 – time for visualization in the AR scene;
- t_6 – time for logging and analytics (optional).

Typically, the first three stages are performed using the standard HttpClient.get() mechanism used in the Angular framework [17]. Then the total time required to transfer the AR models is as follows:

$$T\Sigma = T1 + T2 = \sum_{i=1}^{3} t_i + \sum_{j=4}^{6} t_j, \quad (1)$$

where $T1$ – time spent using the HttpClient.get() method; $T2$ – time spent using other methods.

All stages are executed within the main thread, which may lead to blocking of the user interface (UI). This implies that, in cases involving large model sizes or computationally intensive processing, delays in rendering or temporary UI freezing may occur. Such behavior is generally perceived negatively by users; therefore, a time threshold $TMAX$ is typically defined for the total processing duration $T\Sigma$:

$$T\Sigma < TMAX. \quad (2)$$

In multi-model AR, the third stage typically accounts for the largest portion of the total processing time. Therefore, if condition (2) is violated, it is proposed to use Web Workers instead of the standard HttpClient.get() mechanism.

While handling HTTP requests related to AR model transmission, Web Workers offer potential benefits in terms of performance; however, they also present several drawbacks:

- you can load the model in the web worker, but inserting it into the scene is impossible without passing it back to the main thread;
- difficult transfer of "heavy" resources back to the main thread;
- Web Worker cannot participate in the rendering loop or event handling;
- Web Worker needs to manually transfer resources.

However, the use of web workers enables network operations and data decoding to be performed in the background, without blocking the main application thread, thereby allowing parallel updates of the user interface. As a result, the main thread is freed from handling requests, which enables uninterrupted event processing and UI rendering, reducing the overall perceived latency for the user, therefor

$$T\Sigma = t_1 + t_2 + \sum_{j=4}^{6} t_j + t_7, \quad t_7 << t_3, \quad (3)$$

where t_7 – the time required to transfer the generated models to the main thread.

VI. Research of a Method for Transmitting Multi-Model Augmented Reality Objects

A. Client application testing

At the first stage of the study, testing of both the basic and the modified client application was conducted.

The testing process of the client application with augmented reality elements was carried out in several stages (Fig. 3).

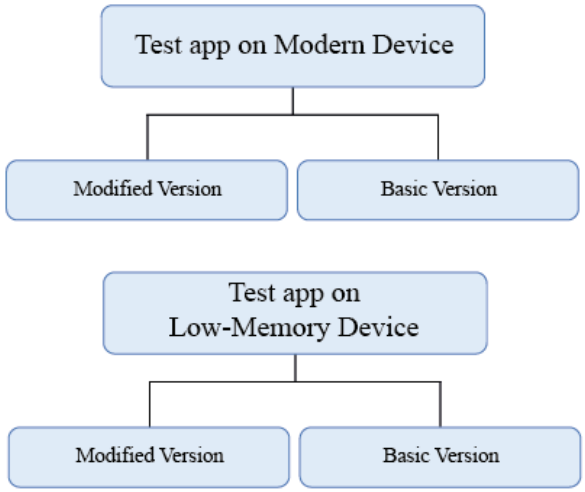


Fig. 3. Scheme of testing a client application with augmented reality elements

The efficiency evaluation was conducted by measuring the time required to load a single 3D model of 16.4 MB in two versions of the application: the modified version (using web workers) and the basic version (based on HttpClient.get()). The testing was carried out using both a modern device and a device with limited RAM capacity.

As a modern device, the Google Pixel 8 smartphone (2023), equipped with 8 GB of RAM, was used. Based on six test runs, the results were obtained and are presented in Table 2.

TABLE II. 3D OBJECT LOADING TIME ON THE MODERN DEVICE

Test	Version loading time, sec	
	modified	***basic***
1	3.06	7.46
2	3.44	8.41
3	5.45	8.08
4	4.67	7.91
5	3.56	7.74
6	3.68	7.80
Average value	**3.98**	**7.90**

The modified version of 3D object loading on a modern device demonstrates higher performance, providing an average 49.62% faster loading speed compared to the basic version.

The device with limited RAM used in testing was a Xiaomi Redmi 4X smartphone, released in 2017, with 3 GB of RAM. The results of the experiment are presented in Table 3.

TABLE III. 3D OBJECT LOADING TIME ON THE DEVICE WITH LIMITED RAM

Test	Version loading time, se	
	modified	***basic***
1	6.92	11.30
2	5.91	13.09
3	5.88	10.11
4	7.04	9.72
5	6.39	9.62
6	9.33	9.38
Average value	**6.91**	**10.54**

Based on the results in Table 3, it was found that the modified version demonstrates higher performance, providing an average 34.45% faster loading speed compared to the basic version.

Figure 4 presents a comparative analysis of 3D object loading time depending on the type of device and application version.

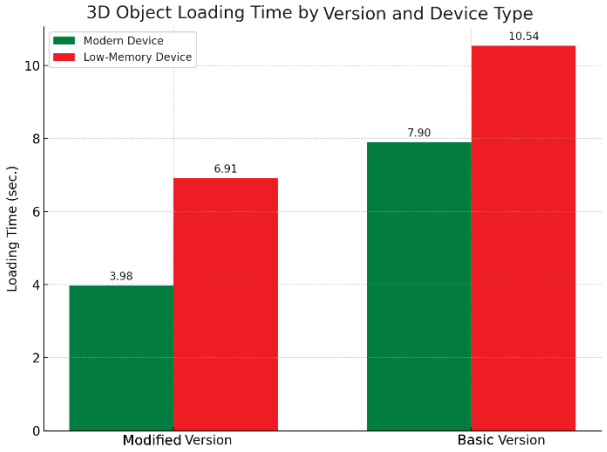

Fig. 4. Comparison of average 3D object load times across different devices and versions

The comparison of the graphs demonstrates that the amount of RAM has a significant impact on loading speed. Specifically, the modified version on a modern device loads 42.40% faster than on a device with limited memory. In the case of the basic version, this difference is 25.05%.

B. Evaluation of the effectiveness of the proposed method

The effectiveness of the proposed method was studied using a model of the functioning of a client application with augmented reality technology. The values analyzed in the model were specified in arbitrary units:

- total time required to transfer AR models ($T\Sigma$);
- total amount of multi-model AR objects ($V\Sigma$);
- total amount of computing resource allocated for transmitting AR models ($R\Sigma$).

In Fig. 5–8 the following notations are introduced:

- B – basic method;
- M – modified method.

The nature of the dependence of the total time required to transfer AR models on the total volume of multi-model AR objects is shown in Fig. 5 ($R\Sigma = 1$) and Fig. 6 ($R\Sigma = 10$).

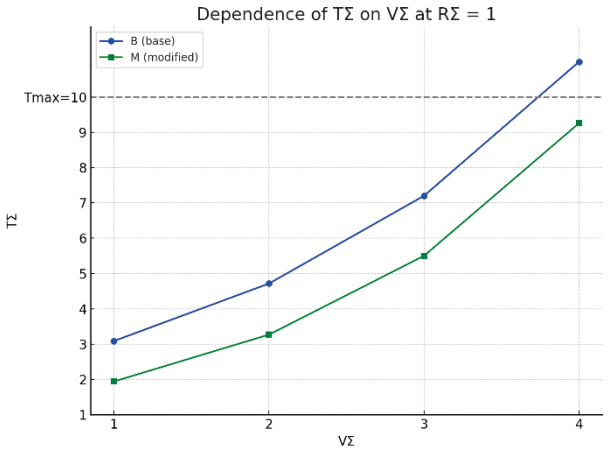

Fig. 5. Dependence of $T\Sigma$ on the total volume of multi-model AR objects at $R\Sigma = 1$

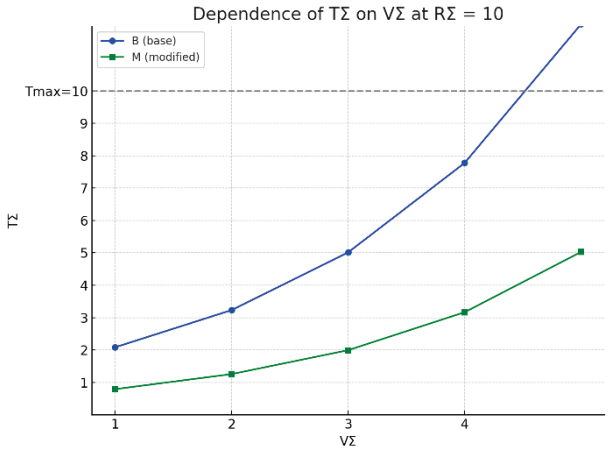

Fig. 6. Dependence of $T\Sigma$ on the total volume of multi-model AR objects at $R\Sigma = 10$

The nature of the dependence of the total time on the total amount of computing resources allocated for the transfer of AR models is shown in Fig. 7 ($V\Sigma = 1$, $V\Sigma = 4$) and Fig. 8 ($V\Sigma = 10$).

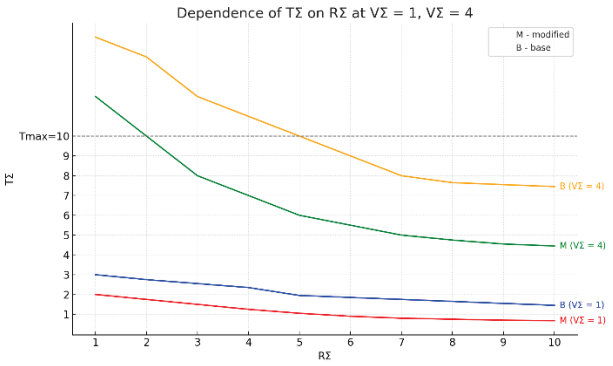

Fig. 7. Dependence of $T\Sigma$ on the total amount of computing resources allocated for the transmitting of AR models at $V\Sigma = 1$ and 4

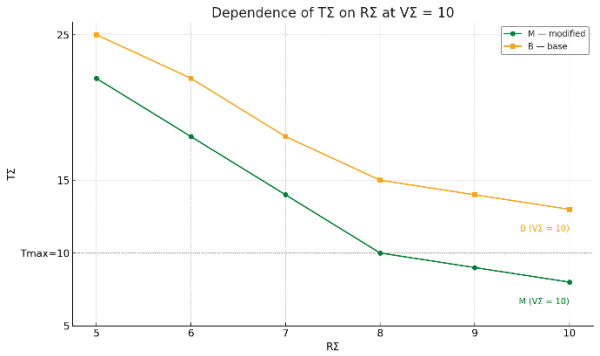

Fig. 8. Dependence of $T\Sigma$ on the total amount of computing resources allocated for the transmitting of AR models at $V\Sigma = 10$

VII. Discussion of Results and Conclusions

This study substantiates the relevance of developing and using a client application with augmented reality (AR) technology. An analysis of AR technology was conducted, various tools for implementing AR were reviewed, and existing works on the development of AR websites were examined.

Based on the conducted analysis, appropriate tools were selected for the development of a client application with AR functionality. A client-side AR application was developed and tested with sample use cases. Additionally, a modification to the basic method of handling HTTP requests related to AR model transmitting was proposed. Specifically, the use of web workers was suggested for processing requests and handling responses.

Comparison of the basic and modified methods based on the operational model of the client application using augmented reality technology demonstrated the universal feasibility of applying the modified method. Specifically, at a value of $R\Sigma = 1$, the efficiency gain from using the modified method is less pronounced. However, as the available computational resources increase, the modified method provides stable performance metrics. Starting from $R\Sigma > 8$, it clearly outperforms the basic method, ensuring compliance with the time constraints (2) at $V\Sigma = 10$ and for $R\Sigma > 2$ at $V\Sigma = 4$. Therefore, the modified method is suitable for use across a wide range of scenarios, regardless of conditions.

Abstract*—This study investigates the synthesis, structural characteristics, and transformative properties of iron-based nanoparticles obtained via electric spark treatment of iron granules in water and organic liquids. Advanced analytical methods, including scanning electron microscopy (SEM), X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), and differential scanning calorimetry (dsc), were utilized to evaluate nanoparticle size, shape, phase composition, and crystal lattice parameters. Results revealed nanoparticles predominantly in α-Fe, γ-Fe, FeO, and Fe_3O_4 phases, demonstrating significant structural heterogeneity and increased lattice distortion due to high dislocation densities (2×10^{14}–6×10^{14} cm^{-2}). Thermodynamic analyses illustrated distinct phase transformation behaviors compared to bulk iron, characterized by reduced transformation temperatures and narrower intervals. Practical application as microstructural modifiers was explored by incorporating these nanoparticles into 45L steel, significantly refining ferrite and pearlite grain structures and enhancing structural homogeneity. This research underscores the electric spark method's efficacy in tailoring iron-based nanoparticles' structural and energetic properties, highlighting their potential for advanced metallurgical applications and materials engineering innovations.*

I. Introduction

Existing research work outlines that a feature of a material in the nanoscale state is the presence of a large number of atoms with uncompensated bonds on its surface [1-5]. This predetermines nanoobjects' increased free surface energy and their intensive interaction with the environment.

Among the numerous methods for producing metal nanoparticles, electric spark treatment of granules in a liquid is the most promising. Such a process combines complex temperature and deformation effects in forming nanoobjects with the high manufacturability of the method. Works [2-8] show that in the process of electric spark treatment, erosion products are formed at high temperatures, pressures, and cooling rates, which creates prerequisites for forming energy-saturated highly dispersed nanoobjects with a wide range of structural states and properties.

Taking into account the high efficiency of the use of nanoparticles [9-12], including those obtained by electric spark treatment of metal granules in liquids, it was of interest to study the possibility of obtaining iron-containing nanoparticles using this method, their chemical composition, structure, and patterns of phase transformations, and to assess the effectiveness of their effect on the structure of iron-carbon alloys.

II. Materials and Methods

The object of the study was nanoparticles obtained in the process of electric spark treatment of iron granules in liquids, according to the methods described in the works [1-8]. Granules and electrodes were made of material of the following chemical composition (% (wt): 0.025C, 0.25Mn, 0.015P, 0.10S, 0.08Si, 0.10Cu, the rest was Fe. Water and organic solutions were used as working fluids.

The particle size, shape, and chemical composition were determined using scanning electron microscopes Jeol-6490LV, Jeol JSM6360, and Hitachi SU8000 SC200D.

The phase composition, parameters of the crystal lattice of nanoparticles, and the size of subgrains (blocks, regions of coherent scattering (CRP)) were studied by X-ray diffraction in monochromatic Cu Kα-radiation on the DRON-UM1 diffractometer. X-ray photoelectron spectroscopy (XPS) on the ES-2401 spectrometer analyzed the chemical composition of the nanoparticle surface. The charge state of iron and oxygen atoms was determined by the bonding energies of Fe2p3/2 and O1s electrons with the atoms.

The regularities of phase transformations were studied using the STA 449 F1 Jupiter thermal analyzer using the method of synchronous thermal analysis. The thermal effects of phase transformations (dsc), the change in mass (TG) of

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

nanoparticles during heating and cooling in argon at a rate of 20 °C/min, were also measured simultaneously. The accuracy of temperature measurement was ± 0.25%, enthalpy - ±3%, mass - ±2 μg.

To assess the effectiveness of nanoparticles obtained during electric spark treatment of iron, their effect on the microstructure of 45L steel in the cast state and after annealing at 860 °C was studied. The microstructure of 45L steel was studied in its initial state (without nanoparticle additives) and after processing the melt with nanoparticles.

III. Research results

Thermodynamic analysis of the characteristics during electric spark treatment of metals in a liquid shows that the process is accompanied by the decomposition of the working medium in the case of water, as well as the formation of oxidizing agents (O, O2, H_2O, OH) and reducing agents (H_2, H), in an organic liquid - C, CO, CO_2 and other compounds. This creates prerequisites for both oxidation and reduction of electrospark erosion products.

X-ray diffraction analysis of the phase composition of nanoparticles indicates that, depending on the technological parameters of their production, nanoparticles α- and γ-Fe, FeO, and Fe_3O_4 oxides are formed.

When nanoparticles are formed in water, their sizes vary from 15 to 60 nm (Fig. 1, a) and from 160 to 700 nm (Fig. 1, b), in an organic liquid, from 10 to 20 nm (Fig. 1, c). The average size values are 30, 380, and 15 nm. The shape coefficient of nanoparticles (the maximum size ratio to the minimum) varies from 1 to 2.4.

X-ray diffraction analysis showed that the sizes of subgrains of α-Fe, γ-Fe, FeO, and Fe3O4 nanoparticles vary from 1 to 93 nm with mean values of 39, 15, 4, and 1 nm, respectively (Table 1). Therefore, the following nanoparticle structure is possible depending on the ratio of the size of the D_{NP} nanoparticles and the regions of coherent D_{OC} scattering. In $D_{np} » D_{rcs}$, a single-crystal structure of nanoparticles is most likely; at $D_{np} > D_{rcs}$, the nanoparticles will consist of several subgrains; at $D_{np} >> D_{rcs}$, they will consist of grains containing subgrains.

Diagrams and photographs of the structure of nanoparticles consisting of single crystals, subgrains containing subgrains are shown in Fig. 2. The study of the structure of grain boundaries in a-Fe nanoparticles showed that they consist of groups of several crystal lattices and dislocations disoriented relative to grains (Fig. 3, a). Subgrain boundaries consist of crystal lattices conjugated with contacting subgrains and dislocations in places where the atomic planes of one of the subgrains are not conjugated and broken (Fig. 3, b).

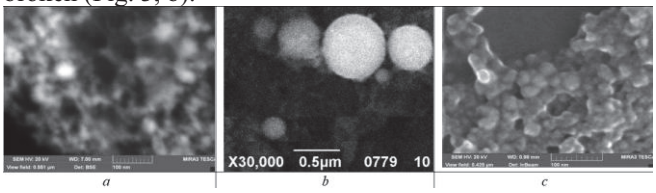

Fig. 1. Sizes of nanoparticles obtained in the electric spark treatment of iron granules in water (a, b) and organic liquid (c).

TABLE I. Sizes (nm) of subgrains (blocks) of the studied nanoparticles

Dimension parameter	Type of Nanoparticles			
	α-Fe	*γ-Fe*	*FeO*	*Fe_3O_4*
Minimum	15	7	3	≈1
Maximum	93	24	6	≈1
Average	39	15	4	≈1

The size of crystal lattices has been studied. Nanoparticles α- and g-Fe obtained in an organic liquid are characterized by higher values of crystal lattice parameters than massive materials (Fig. 4, a, b). The opposite pattern is observed for FeO and Fe_3O_4 nanoparticles obtained in water (Fig. 4, c, d).

The size of the crystal lattice of nanoparticles depends on the value of the surface tension, which compresses the nanoparticle and decreases the parameter of its crystal lattice and the content of impurity elements that increase its value. The increase in the crystal lattice parameter of nanoparticles α- and γ-Fe is apparently due to the dissolution of carbon obtained due to the dissociation of an organic liquid in ferrite and austenite. In the case of oxide nanoparticles, they are compressed under the influence of surface tension.

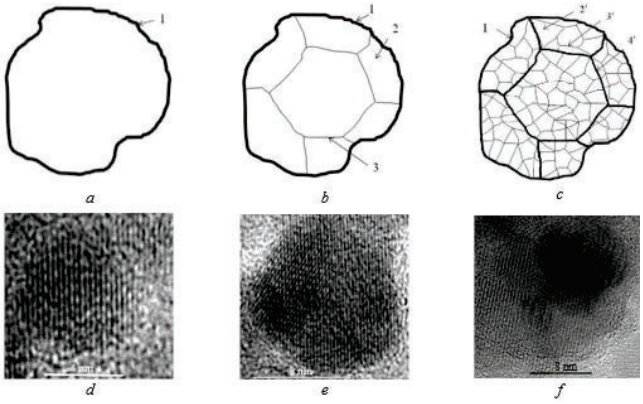

Fig. 2. Diagrams of the structure (a—c) and structure (d—f) of single-crystal (a, d) consisting of subgrains (b, e) and grains containing subgrains (c, f), nanoparticles: 1 — nanoparticle; 2, 2′ — subgrains; 3, 3′ — subgrain boundaries; 4′ — grain boundaries.

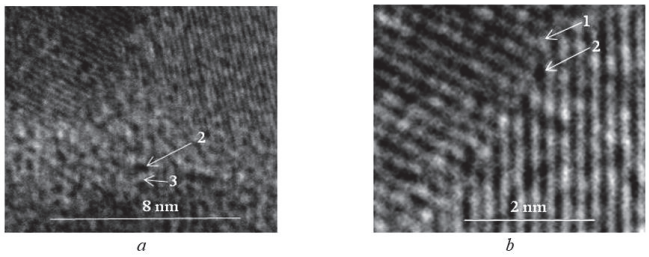

Fig. 3. Structure of the boundaries of grains (a) and subgrains (b) of α-Fe: 1 — crystal lattice conjugated with contacting subgrains; 2 — nucleus of marginal dislocation; 3 — group of crystal lattices disoriented relative to grains.

It should be noted that the dissolution of oxygen formed as a result of water dissociation in FeO and Fe_3O_4 nanoparticles also contributes to a specific decrease in the size of their crystal lattices, since with an increase in the oxygen content in oxides within their homogeneity, there is a decrease in the parameters of their crystal lattices [13-15].

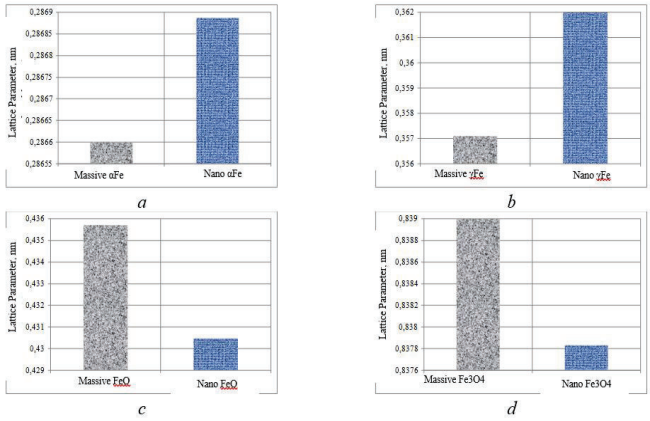

Fig. 4. Parameters of crystal lattices of massive materials and nanoparticles α-Fe (a), γ-Fe (b), FeO (c), and Fe3O4 (d) obtained by electric spark treatment of iron granules in organic liquid (a, b) and water (c, d).

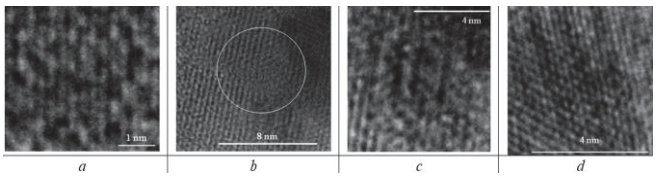

Fig. 5. Defects in the crystal structure of a-Fe nanoparticles: a, b-dislocations; c-the source of the Frank-Reed dislocations; d-doubles.

The study of the fine structure has shown that in the process of electric spark processing of granules, nanoparticles are formed with such defects in the crystal structure as dislocations and twins, as well as sources of generation of linear defects (Fig. 5). Distortion of crystal lattices is observed around the nuclei (Fig. 5, a) and dislocation loops (Fig. 5, b). Analysis of the defects in the crystal structure shown in Fig. 5 showed that in nanoparticles a-Fe, there is a chaotic distribution of dislocations with a density of 2×10^{14} to 6×10^{14} cm^{-2}.

Known technological operations for hardening of massive metals and alloys [16-20] make it possible to obtain the following levels of dislocation density:

- from 10^8 up to 10^{11} cm^{-2} in case of plastic deformity;
- from 10^{10} to 10^{12} cm^{-2} as a result of phase transformations (for example, the formation of martensite);
- up to 10^{13} cm^{-2} when intense plastic deformation and phase transformations are combined, or under nonequilibrium crystallization conditions (e.g., high-velocity galvanic deposition in a cold electrolyte or sputtering with a high-density ion beam on an intensively cooled substrate).

The level of dislocation density in nanoparticles obtained in the process of electric spark treatment (~10^{14} cm-2) approached the limit. It reached more than 103—104 °C/s as a result of the combined action of shock waves arising in the process of pulsed expansion of electric spark channels under the influence of pressure of about a dozen megapascals and a high cooling rate of more than 103—104 °C/s. The level of the lower limit of the nanoparticle cooling rate was determined based on the condition that g-Fe fixation at room temperature and normal pressure is possible at a cooling rate of more than 103—104 °C/s.

Comparison of the density of dislocations in nanoparticles and massive materials obtained by known methods shows that the level of defects in the crystal structure of nanoparticles after electric spark treatment is much higher than the values achieved by known hardening metals and alloys. A high level of dislocation density in nanoparticles predetermines their high energy saturation, because the main contribution to the energy of the substructure and subgrain boundaries is made by the elastic energy of dislocations, which, in the case of the presence of boundary and helical dislocations, is determined by the following dependence:

$$\Delta U = \frac{\rho G}{4\pi} \cdot ln\frac{R}{r_n} \cdot \left(\frac{b_k^2}{(1-\nu)} + b_c^2\right), \quad (1)$$

,where ρ is the density of dislocations; G is the shear modulus; r_n is the radius of the nucleus of dislocations; R is the shielding radius of the elastic field of dislocations (in the first approximation, it is equal to the average distance between dislocations); b_k and b_c are the Burgers vector of marginal and helical dislocation, respectively; n is Poisson's ratio.

Analysis of experimental data from differential scanning calorimetry (dsc) (Fig. 6), thermogravimetry, electron microscopy (Fig. 7, 8) and the results of thermodynamic calculations allows us to interpret the process of phase transformations in nanoparticles obtained by electric spark treatment of iron granules in an organic liquid and containing 45.5% α-Fe and 54.5% γ-Fe as follows. In the first heating of nanoparticles, polymorphic transformations began at 230 °C with a γ-Fe -> α-Fe transformation that reached a maximum at 336 °C and ended at 390 °C. At 397 °C, the oxygen-containing film covering the nanoparticles began to break down. The process ended with the formation of Fe_3O_4 oxide and oxygen at 460 Reduction of iron from Fe_3O_4 with carbon was fixed at 597 °C and ended at 800 °C (Fig. 6).

Analysis of the data given in Fig. 7 showed that at the first heating of nanoparticles, the temperature of the beginning of the conversion of α-Fe to γ-Fe decreased by 4% compared to the equilibrium value. The interval of conversion of α-Fe to γ-Fe in nanoparticles was 90 °C. A feature of phase transformations in nanoparticles was that after α-Fe -> γ-Fe transformation in the interval of 800-1050 °C, austenite and graphite appeared in them, which began to dissolve in austenite at temperatures of 1050-1070 °C (Fig. 6). At the same time, the temperature of coexistence of austenite and graphite was 250 °C, and the dissolution temperature of graphite was 20 °C with a ratio of 93 and 7%, respectively.

In massive iron, the dissolution of graphite began immediately after α-Fe -> γ-Fe- Transformations (738^{OS}) and lasted until 1038^{OS}. At the same time, the temperature changed insignificantly and amounted to 270 and 300, respectively, ^{OS}.

Research results showed that the temperature intervals of phase transformations, as a result of which gaseous products of reactions were formed, correlated with a decrease in the mass of the system, and amounted to 3.24 and 6.19%.

The transformation of α-Fe → γ-Fe occurred in the temperature range of iron reduction and began at temperatures ≈705-710 °C, and ended at 800 °C. In the range of 1050-1070 °C, graphite dissolved in austenite, which at 1132.7 °C begins to melt and at 1172 °C completely turns into a liquid state.

In the process of cooling the melt in the temperature range from ≈1125 to 1040 °C, austenite was formed, from which graphite begins to be released at 1109 °C and 930 °C. The formation of graphite is because the heat treatment of nanoparticles was carried out under conditions of low cooling rates (20 °C/min), which is less than the critical rate (35 °C/min), and the excess of which leads to the separation of cementite from austenite. The conversion of γ-Fe → α-Fe begins at 692 and ends at 643 °C.

When the cooled material is reheated, the conversion of α iron into γ iron, the dissolution of graphite in γ iron, and the melting of austenite are completed at lower temperatures than in the first case. At the same time, the temperature intervals of phase transformations are reduced, respectively, by 50, 5, and 27% compared to the first heating. In the process of cooling after the 2nd heating, identical phase transformations are observed in the temperature ranges close to cooling after the first heating.

More significant differences were observed in the analysis of the temperature range of austenite. For nanoparticles, the process of dissolution of graphite in austenite ends at a temperature 10-30 °C higher than in massive iron, but the temperature range of austenite existence is 3-4 times shorter than in ordinary iron lower than in massive material, while the temperature range of the process is reduced by 5-6 times.

In the process of cooling the liquid metal obtained after melting the nanoparticles, solidification begins with the release of austenite, the formation temperature of which is 340-350 ^{OS} lower, and the temperature interval of the process is 2-3 times shorter than that of massive iron. The peculiarity of solidification is that austenite and graphite are almost simultaneously separated from the liquid phase, and the total temperature range of their existence before the beginning of the γ-Fe → α-Fe transition into 1,7-1.8 times less than conventional iron.

The results of measuring the heat of phase transformations observed when heating nanoparticles (Fig. 6) and comparing them with the data for massive iron showed that when heating nanoparticles, the heat of conversion of γ-iron into α-iron, α-Fe into γ-Fe, and melting of austenite, respectively, is 1.6, 2.1, and 18 times less than the equilibrium values. In the case of cooling of the material obtained after the melting of nanoparticles, the heat of transformation of γ-iron to α-iron is 3.2 times less than the equilibrium iron.

It should be noted that during the repeated heating and cooling of the iron-carbon alloy obtained due to the melting of nanoparticles and solidification, almost identical to nanothe laws of phase transformations. This indicates a significant influence of heredity on the process of formation of material obtained from nanoobjects.

Analysis of the study of the structure and phase transformations in nanoparticles shows that nanoobjects obtained during the electric spark treatment of iron have an increased level of defects in the crystalline structure and other patterns of phase transformations compared to massive iron. This creates the prerequisites for the effective interaction of nanoparticles with the environment, for example, when introduced into liquid metal.

To study the possibility of using nanoparticles as modifiers of the structure of metals and alloys, a series of experiments on the modification of the structure of steel with 45 iron nanoparticles were carried out. The results of inoculation of steel with 45 iron nanoparticles are shown in Fig. 9.

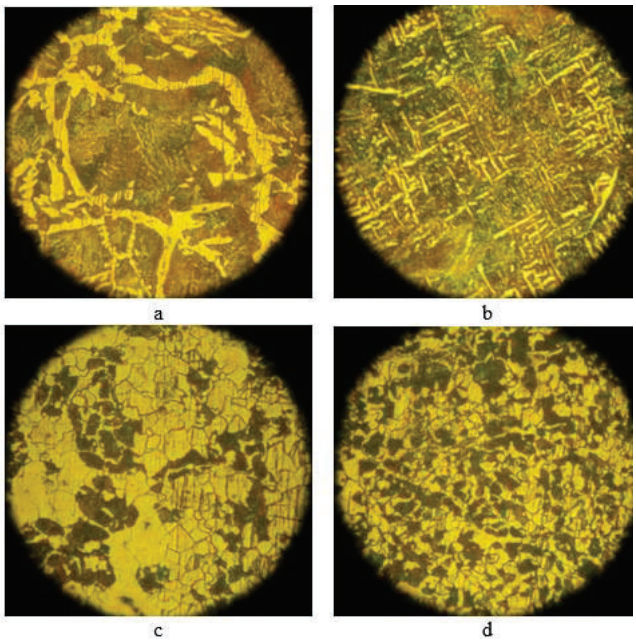

Fig. 9. Effect of nanoparticles (b, d) obtained during electric spark treatment of iron on the microstructure of steel 45L (a, c): a, b - cast state; c, d - annealing at 860 °C (magnification x 100).

In the case of nanoparticles containing iron for processing metal melts, the regularity of their interaction with the melt changes. This is due to the fact that when ordinary iron powder is introduced into a metal melt, the melt is supercooled at the points of its contact with powder particles due to heat consumption for heating and phase $\alpha \rightarrow \gamma$, $\gamma \rightarrow \delta$, $\delta \rightarrow$the liquid of transformation in particles. In the process of processing the melt with nanoparticles containing iron, the melt does not supercool. Still, it overheats at the moment of contact with the nanoparticles when the temperature of $\rightarrow \alpha$-transformation is reached.

Quantitative computer analysis of microstructures (Fig. 9) showed that after inoculation of 45L steel with nanoparticles, the amount of pearlite in the cast state increased from 62.6 to 72.5%, that is, by 16%, and after annealing, from 46.7 to 66.1%, that is, by 42%. Statistical analysis of changes in the microstructure shows that spheroidization of grains, a decrease in their size, and a narrowing of the size range by 6 times are observed. Inoculation led to the dispersion of ferrite grains in the cast state by 2.3-2.4 times and to an increase in the homogeneity of the structure by 1.7-2.4 times. After annealing, the size of ferrite grains decreased by 1.2-2.4 times, and perlite by 1.2-1.5 times, while the homogeneity of the structure increased by 1.2-1.8 times.

IV. CONCLUSIONS

Through rigorously documented experimental procedures, this study has demonstrated that electric spark treatment of iron granules in liquid media is an effective and controllable method for synthesizing iron-based nanoparticles with tailored size distribution, phase composition, and lattice characteristics. Comprehensive structural and thermodynamic characterization was carried out using scanning electron microscopy (Jeol-6490LV, Jeol JSM6360, Hitachi SU8000 SC200D) for morphology and particle size, X-ray diffraction (DRON-UM1, Cu Kα radiation) for phase identification and coherent scattering region size determination, X-ray photoelectron spectroscopy (ES-2401) for surface chemical state analysis, and synchronous thermal analysis (STA 449 F1 Jupiter) for DSC/TG measurements, following established and referenced methodological standards.

The experimental results confirmed the synthesis of nanoparticles predominantly composed of α-Fe, γ-Fe, FeO, and Fe_3O_4 phases, with coherent scattering regions ranging from 1 to 93 nm. The proposed model relating nanoparticle size to crystalline substructure was validated by combining high-resolution microscopy and XRD measurements. Nanoparticles exhibited exceptionally high dislocation densities (2×10^{14}–6×10^{14} cm^{-2}), far exceeding those achievable in conventionally strengthened bulk metals, indicating high structural energy saturation. Differential scanning calorimetry revealed distinct phase transformation behaviors compared to bulk iron, including reduced $\alpha\leftrightarrow\gamma$ transformation onset temperatures, narrower transformation intervals, and shortened austenite stability ranges by factors of three to six, highlighting the influence of nanoscale structure on thermodynamic processes.

The practical applicability of these nanoparticles as steel microstructure modifiers was verified through quantitative metallographic analysis of 45L steel inoculated with the synthesized particles. Using optical microscopy at ×100 magnification with calibrated scale references, it was established that nanoparticle addition increased pearlite content in the cast state by 16% and after annealing at 860 °C by 42%, refined ferrite grain size by up to 2.4 times, reduced pearlite grain size by up to 1.5 times, and enhanced structural homogeneity by up to 2.4 times. These modifications are attributable to the documented interactions between high-energy nanoparticles and the steel melt, supported by the controlled experimental design.

Overall, the findings provide reproducible, verifiable evidence that electric spark–synthesized iron nanoparticles possess unique structural and phase transformation properties that are directly responsible for substantial improvements in steel microstructure. The combination of detailed methodological transparency, precise measurement, and quantitative analysis ensures that the results can be independently validated and applied to advanced metallurgical processing and materials engineering.

***Abstract*— The paper considers modelling of material transportation processes in electrical systems using belt conveyors as an example. The main attention is paid to formalization and construction of similarity criteria necessary for analysis, comparison and design of transport systems with both deterministic and stochastic input material flows. Based on the analysis of equations describing the behaviour of flow parameters of the transported material, a dimensionless transformation is carried out using the π-theorem, which allows identifying the key dimensionless parameters of the model. It is shown that the similarity criteria allow generalizing the results of experiments conducted on one system and extending them to other transport systems, provided that the values of the dimensionless characteristics coincide. This ensures the possibility of a unified approach to the development of energy-saving control systems, even in conditions of incomplete or limited experimental data. The paper constructs tables of parameter dimensions and corresponding similarity criteria for both deterministic and stochastic input models. It is demonstrated that the use of the introduced criteria ensures the equivalence of the models and allows the use of unified numerical solution methods. The presented methods and approaches have practical significance in the design, modelling and optimization of modern transport systems in the mining and electrical engineering industries.**

Keywords*— *conveyor, energy saving, material loading coefficient, similarity criteria

I. Introduction

Modern problem in the field of electrical engineering modelling increasingly require taking into account the interaction of mechanical, energy and information components, especially in the context of production systems control [1]. One such example is conveyor-type transport systems, widely used in the mining and processing industries [2, 3, 4]. Modelling and simulation of such systems for the purpose of optimizing their energy and dynamic characteristics are of considerable interest for the development of intelligent control systems [5, 6, 7, 8].

The results of processing the experimental data on the operation of conveyors make it possible to identify stable patterns in the transportation of material and to assess the influence of various factors on the energy efficiency of the system [9, 10, 11]. However, to transfer these results to new operating conditions in which experimental data are absent, a theoretical basis is needed to generalize the behaviour of the system. Such a basis is modelling using dimensionless parameters and similarity criteria.

This paper is devoted to the construction of a system of dimensionless parameters describing the behaviour of a transport system under deterministic and stochastic modes of material supply. A method for theoretically selecting the minimum required number of determining parameters reflecting key physical phenomena in the most universal form is considered. The resulting models allow for numerical simulation, predicting the behaviour of systems when changing modes, and optimizing flow control from the point of view of energy saving, which is especially important in the context of electro-technical modelling of complex production processes.

II. Problem Statement

In the context of the active implementation of digital modelling methods in electrical engineering systems, the problem of formalizing and transferring experimental results between different objects is becoming especially relevant [12, 13]. In particular, when modelling conveyor transport systems closely related to electric drives and automatic control systems [14, 15], it is necessary to take into account issues of physical and mathematical similarity. One of the key problems is to determine the conditions under which the modelling results or experimental data obtained for one specific transport system can be extrapolated to other systems with different design and operational parameters. In this context, similarity criteria act as a fundamental tool that allows for adequate simulation and the development of universal approaches to material flow management. This is especially important when designing energy-saving optimal control algorithms for conveyor-type transport systems [14, 16], where it is necessary to take into account both deterministic and stochastic components of the flow [17, 18]. In such conditions, the use of dimensionless parameters and similarity criteria becomes not just an auxiliary, but often the only possible theoretical method for constructing and verifying the developed control model.

III. Transport System Model

The conveyor model for describing the process of material transportation is studied in detail in [19] and can be represented in the following form by a partial differential equation:

$$\frac{\partial \chi_0(t,S)}{\partial t}+\frac{\partial \chi_1(t,S)}{\partial S}=\delta(S)\lambda(\mathrm{t}), \tag{1}$$

$$\chi_0(0,S)=H(S)\Psi(S), \tag{2}$$

$$\chi_1(t,S)=a(t)\chi_0(t,S), \tag{3}$$

where $\chi_1(t,S)$, $\chi_0(t,S)$ flow and linear density of the material transported by a conveyor of length S_d at point

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

$S \in [0, S_d]$ at time t; $\Psi(S)$ – linear density of the material at point $S \in [0, S_d]$ at the initial time $t = 0$; $H(S)$, $\delta(S)$ Heaviside function and Dirac function, respectively; $a(t)$ – conveyor belt speed at time t; $\lambda(\mathrm{t})$ – input flow of material entering the transport system at point $S = 0$. For several input flows of material $\lambda_1(\mathrm{t}), \lambda_2(\mathrm{t}), \lambda_3(\mathrm{t})$, entering the conveyor at several points S_1, S_2, S_3 equation (1) takes the form:

$$\frac{\partial \chi_0(t,S)}{\partial t} + \frac{\partial \chi_1(t,S)}{\partial S} = \sum_{k=1}^{3} \delta(S - S_k)\lambda_k(\mathrm{t}). \quad (4)$$

Let us define similarity criteria for conveyors, the process of material transportation for which is determined by equation (1). To construct similarity criteria, we will use the π-theorem. The dimension of each of the defining parameters of the model P_n can be expressed through the basic units of measurement: time $[\mathrm{T}]$, length $[\mathrm{L}]$, mass $[\mathrm{M}]$:

$$[P_n] = [\mathrm{T}]^{\alpha_n}[\mathrm{L}]^{\beta_n}[\mathrm{T}]^{\mu_n}, \quad n = 1...N. \quad (5)$$

The transport system will be characterized by $(N-R)$ similarity criteria:

$$\pi_i = \prod_{n=1}^{N} [\mathrm{P_n}]^{z_{ni}}, \quad i = 1...(N-R). \quad (6)$$

where R is the number of basic units of change. For the transport conveyor model represented by equation (1), $R = 3$ respectively. The exponents of z_{ni} must be defined in such a way that the value of π_i is a dimensionless quantity:

$$\pi_i = \prod_{n=1}^{N} \left([\mathrm{T}]^{\alpha_n}[\mathrm{L}]^{\beta_n}[\mathrm{T}]^{\mu_n}\right)^{z_{ni}}, \quad i = 1...(N-R). \quad (7)$$

The values of the exponents of degree z_{ni} under this condition are determined from the solution of the system of equations:

$$\sum_{n=1}^{N} \alpha_n z_{ni} = 0, \quad \sum_{n=1}^{N} \beta_n z_{ni} = 0, \quad \sum_{n=1}^{N} \mu_n z_{ni} = 0. \quad (8)$$

The system of equations has $(N-R)$ independent solutions. Each solution is assigned a similarity criterion. In a specific study of special classes of material transportation phenomena using conveyors, the numerical values of quantitative characteristics P_n are usually expressed as a ratio to the specified or most characteristic quantities. The parameter based on the Dirac function differs from other variables, such as $\chi_0(t,S)$, $\chi_1(t,S)$, $\lambda(\mathrm{t})$, since it is not scaled directly, but only its argument $S_d\delta(S) = \delta(S/S_d)$ is scaled. This circumstance is the reason that the Dirac function will be singled out as a separate parameter when used in the π-theorem. The presence of this parameter in the equation allows us to construct similarity criteria based on the structure of local sources of material receipt on the conveyor. This is especially useful when constructing similarity criteria for a main conveyor with several sources of material receipt located along the transportation route.

IV. Similarity Criteria for a Model with Deterministic Input Flow of Material

The defining parameters P_n and their dimensionality for the model with a deterministic input material flow are presented in Table 1.

TABLE I. Degrees of Dimensionality of Parameters for a Model with a Deterministic Input Flow of Material

n	parameter, P_n	Basic units of measurement					
		time, [T]		length, [L]		mass, [M]	
1	χ_0	α_1	0	β_1	-1	μ_1	1
2	χ_1	α_2	-1	β_2	0	μ_2	1
3	λ	α_3	-1	β_3	0	μ_3	1
4	$\delta(S)$	α_4	0	β_4	-1	μ_4	0
5	t	α_5	1	β_5	0	μ_5	0
6	S	α_6	0	β_6	1	μ_6	0

Taking into account the values of the exponents α_n, β_n, μ_n the system of equations (8) for the deterministic model can be written in the following form:

$$\begin{cases} -z_{2i} - z_{3i} + z_{5i} = 0, \\ -z_{1i} - z_{4i} + z_{6i} = 0, \\ z_{1i} + z_{2i} + z_{3i} = 0, \end{cases} \quad i = 1,2,3. \quad (9)$$

where the number of defining parameters is $N = 6$, with the number of basic units of measurement being $R = 3$. The system of equations (9) has three degrees of freedom $(N-R)$. Three quantities z_{ni} can take arbitrary values, the other three are determined by the system of equations (9). The freedom in choosing these quantities does not affect the similarity criteria of the transport conveyor, which allows us to determine simple values for them. In this regard, we will define variables $z_{1i} = \omega_{1i}$, $z_{2i} = \omega_{2i}$, $z_{4i} = \omega_{3i}$, where $\omega_{1i}, \omega_{2i}, \omega_{3i}$ are arbitrary simple values. Having performed the transformation:

$$\begin{cases} z_{5i} = -z_{2i} - z_{3i} = -z_{1i}, \\ z_{6i} = z_{1i} + z_{4i}, \\ z_{3i} = -z_{1i} - z_{2i}, \end{cases} \quad i = 1,2,3. \quad (10)$$

we obtain a general solution to the system of equations (9):

$$\begin{cases} z_{1i} = \omega_{1i}, \\ z_{2i} = \omega_{2i}, \\ z_{3i} = -\omega_{1i} - \omega_{2i}, \\ z_{4i} = \omega_{3i}, \\ z_{5i} = -\omega_{1i}, \\ z_{6i} = \omega_{1i} + \omega_{3i}, \end{cases} \quad i = 1,2,3. \quad (11)$$

We substitute three different sets of $\omega_{1i},\omega_{2i},\omega_{3i} \in \{0,1\}$ and determine the values of z_{ni} . The solution of equation (9) and for different sets of $\omega_{1i},\omega_{2i},\omega_{3i}$ and the similarity criteria corresponding to these solutions for the deterministic conveyor model are presented in Table 2.

TABLE II. SIMILARITY CRITERIA FOR A MODEL WITH DETERMINISTIC INPUT FLOW OF MATERIAL

i	ω_{1i}	ω_{2i}	ω_{1i}	z_{1i}	z_{2i}	z_{3i}	z_{4i}	z_{5i}	z_{6i}	**Similarity criteria**
1	1	0	0	1	0	-1	0	-1	1	$\pi_1 = \frac{\chi_0 S}{t\lambda}$
2	0	1	0	0	1	-1	0	0	0	$\pi_2 = \frac{\chi_1}{\lambda}$
3	0	0	1	0	0	0	1	0	1	$\pi_3 = S_d\delta(S)$

Let the considered process of material transportation be characterized by the parameters: χ_0^* , χ_1^*, λ^* , t^*, S^* . Let us introduce dimensionless modelling parameters for the considered process of material transportation:

$$\tau = \frac{t}{t^*},\ \xi = \frac{S}{S^*},\ \Theta_0 = \frac{\chi_0}{\chi_0^*},\ \delta(\xi) = S^*\delta(S), \qquad (12)$$

$$g(\tau) = a(t)\frac{t^*}{S^*},\quad \Theta_1 = \frac{\chi_1}{\chi_1^*},\quad \gamma = \frac{\lambda}{\lambda^*}. \qquad (13)$$

Then equation (1) can be rewritten as:

$$\frac{\chi_0^*}{t^*}\frac{\partial\Theta_0(\tau,\xi)}{\partial\tau} + \frac{\chi_1^*}{S^*}\frac{\partial\Theta_1(\tau,\xi)}{\partial\xi} = \frac{\lambda^*}{S^*}\delta(\xi)\gamma(\tau). \qquad (14)$$

We divide both parts of the equation by the factor $\left(\lambda^*/S^*\right)$, and obtain equation (1) in dimensionless form:

$$\frac{S^*}{\lambda^*}\frac{\chi_0^*}{t^*}\frac{\partial\Theta_0(\tau,\xi)}{\partial\tau} + \frac{S^*}{\lambda^*}\frac{\chi_1^*}{S^*}\frac{\partial\Theta_1(\tau,\xi)}{\partial\xi} = \delta(\xi)\gamma(\tau). \qquad (15)$$

The dimensionless factors in equation (15) represent the similarity criteria (Table 2). Using the notation for the similarity criteria, we rewrite equation (15) as an equation containing the similarity criteria:

$$\pi_1\frac{\partial\Theta_0(\tau,\xi)}{\partial\tau} + \pi_2\frac{\partial\Theta_1(\tau,\xi)}{\partial\xi} = \pi_3\gamma(\tau). \qquad (16)$$

Let us supplement equation (16) with equations (2), (3) in dimensionless form:

$$\Theta_1(\tau,\xi) = \frac{\pi_1}{\pi_2}g(\tau)\Theta_0(\tau,\xi), \qquad (17)$$

$$\Theta_0(0,\xi) = H(\xi)\psi(\xi), \qquad (18)$$

a system of equations for describing the behaviour of the flow parameters of a transport system with a deterministic input flow of material is obtained. From the presented dimensionless system of equations, one can draw a very important conclusion: for different conveyor systems, for which the values of the similarity criteria π_1 , π_2 , π_3 are close in value, the behaviour of the dimensionless flow parameters will be described by the same equation.

V. SIMILARITY CRITERIA FOR A CONVEYOR MODEL WITH STOCHASTIC STATIONARY INPUT MATERIAL FLOW

Let the stochastic stationary input flow of material be determined by realization $\lambda(t)$, the values of which are obtained as a result of experimental measurements [20, 21, 22]. The input flow of material under consideration will be characterized by the mathematical expectation m_λ , the standard deviation σ_λ and the correlation time η . To analyse the input flow of material, we introduce the variable γ :

$$\lambda = m_\lambda + \gamma\sigma_\lambda,\quad \gamma = \frac{\lambda - m_\lambda}{\sigma_\lambda}. \qquad (19)$$

Taking into account the features of additional parameters, that characterize the input flow of material, the defining parameters P_n and their degrees of dimensionality for the model with a stochastic input flow of material are presented in Table 3.

TABLE III. DEGREES OF DIMENSIONALITY OF PARAMETERS FOR A CONVEYOR MODEL WITH STOCHASTIC INPUT MATERIAL FLOW

n	**parameter,** P_n	**Basic units of measurement**					
		time, [T]		**length, [L]**		**mass, [M]**	
1	χ_0	α_1	0	β_1	-1	μ_1	1
2	χ_1	α_2	-1	β_2	0	μ_2	1
3	m_λ	α_3	-1	β_3	0	μ_3	1
4	$\delta(S)$	α_4	0	β_4	-1	μ_4	0
5	t	α_5	1	β_5	0	μ_5	0
6	S	α_6	0	β_6	1	μ_6	0
7	σ_λ	α_7	-1	β_7	0	μ_7	1
8	η	α_8	1	β_8	0	μ_8	0

Let us take into account the values of the exponents α_n , β_n , μ_n and, by analogy with the model for a deterministic input flow of material, we will represent the system of equations (8) in the following form:

$$\begin{cases} -z_{2i} - z_{3i} + z_{5i} - z_{7i} + z_{8i} = 0, \\ -z_{1i} - z_{4i} + z_{6i} = 0, \\ z_{1i} + z_{2i} + z_{3i} + z_{7i} = 0, \end{cases} \quad i = 1,...,5. \qquad (20)$$

where the number of defining parameters is $N = 8$ with the number of basic units of measurement being $R = 3$. The resulting system of equations (20) has five degrees of freedom $(N - R)$. Five quantities z_{ni} can take arbitrary values, the

remaining three are determined by the system of equations (20). Having performed the transformation:

$$\begin{cases} z_{5i} = -z_{1i} - z_{8i}, \\ z_{6i} = z_{1i} + z_{4i}, \\ z_{3i} = -z_{1i} - z_{2i} - z_{7i}, \end{cases} \quad i = 1,...,5. \tag{21}$$

a general solution to the system of equations (20) is obtained:

$$\begin{cases} z_{1i} = \omega_{1i}, \\ z_{2i} = \omega_{2i}, \\ z_{3i} = -\omega_{1i} - \omega_{2i} - \omega_{4i}, \\ z_{4i} = \omega_{3i}, \\ z_{5i} = -\omega_{1i} - \omega_{5i}, \\ z_{6i} = \omega_{1i} + \omega_{3i}, \\ z_{7i} = \omega_{4i}, \\ z_{8i} = \omega_{5i}, \end{cases} \quad i = 1,...,5. \tag{22}$$

Let's select five different sets $\omega_{ki} \in \{-1,0,1\}$ $k = 1,...,5$ to determine the value of z_{ni}. The solution of equation (9) for different sets ω_{ki} and the corresponding similarity criteria for the conveyor model with a stochastic input material flow are presented in Table 4.

TABLE IV. SIMILARITY CRITERIA FOR A MODEL WITH STOCHASTIC INPUT MATERIAL FLOW

i	z_{1i}	z_{2i}	z_{3i}	z_{4i}	z_{5i}	z_{6i}	z_{7i}	z_{8i}	**Similarity criteria**
1	$\omega_{k1} = (1,0,0,0,0)$								$\pi_1 = \frac{\chi_0 S}{t m_\lambda}$
	1	0	-1	0	-1	1	0	0	
2	$\omega_{k2} = (0,1,0,0,0)$								$\pi_2 = \frac{\chi_1}{m_\lambda}$
	0	1	-1	0	0	0	0	0	
3	$\omega_{k3} = (0,0,1,0,0)$								$\pi_3 = S_d \delta(S)$
	0	0	0	1	0	1	0	0	
4	$\omega_{k4} = (0,0,0,1,0)$								$\pi_4 = \frac{\sigma_\lambda}{m_\lambda}$
	0	0	-1	0	0	0	1	0	
5	$\omega_{k5} = (0,0,0,0,-1)$								$\pi_5 = \frac{t}{\eta}$
	0	0	0	0	1	0	0	-1	

It is assumed that the studied process of material transportation can be characterized by the parameters: χ_0^*, χ_1^*, m_λ^*, σ_λ^*, η^*, t^*, S^*. Let us introduce dimensionless modelling parameters for the considered process of material transportation:

$$\tau = \frac{t}{t^*},\ \xi = \frac{S}{S^*},\ \Theta_0 = \frac{\chi_0}{\chi_0^*},\ \delta(\xi) = S^* \delta(S), \tag{23}$$

$$\Theta_1 = \frac{\chi_1}{\chi_1^*},\ \psi = \frac{\Psi}{\chi_0^*},\ g(\tau) = a(t)\frac{t^*}{S^*},\ \gamma = \frac{\lambda - m_\lambda^*}{\sigma_\lambda^*}, \tag{24}$$

Then equation (1) can be rewritten as:

$$\frac{\chi_0^*}{t^*}\frac{\partial \Theta_0(\tau,\xi)}{\partial \tau} + \frac{\chi_1^*}{S^*}\frac{\partial \Theta_1(\tau,\xi)}{\partial \xi} = \frac{\delta(\xi)}{S^*} m_\lambda \left(1 + \frac{\sigma_\lambda}{m_\lambda}\gamma(\tau)\right). \tag{25}$$

Let's divide both parts of the equation by a factor of $\left(m_\lambda / S^*\right)$, and obtain equation (1) in dimensionless form:

$$\frac{S^*}{m_\lambda}\frac{\chi_0^*}{t^*}\frac{\partial \Theta_0(\tau,\xi)}{\partial \tau} + \frac{S^*}{m_\lambda}\frac{\chi_1^*}{S^*}\frac{\partial \Theta_1(\tau,\xi)}{\partial \xi} = \delta(\xi)\left(1 + \frac{\sigma_\lambda}{m_\lambda}\gamma\left(\tau\frac{t^*}{\eta^*}\right)\right). \tag{26}$$

Taking into account the notations for the similarity criteria (Table 4), equation (26) can be represented in a form containing the similarity criteria:

$$\pi_1 \frac{\partial \Theta_0(\tau,\xi)}{\partial \tau} + \pi_2 \frac{\partial \Theta_1(\tau,\xi)}{\partial \xi} = \pi_3\left(1 + \pi_4 \gamma(\pi_5 \tau)\right). \tag{27}$$

Let us supplement equation (27) with equations (2), (3) in dimensionless form:

$$\Theta_1(\tau,\xi) = \frac{\pi_1}{\pi_2} g(\tau)\Theta_0(\tau,\xi), \tag{28}$$

$$\Theta_0(0,\xi) = H(\xi)\psi(\xi), \tag{29}$$

a system of equations for describing the behaviour of the flow parameters of a transport system with a stochastic input flow of material is obtained. Different conveyor systems for which the values of the similarity criteria π_1,…, π_5 have close values are similar systems. These conveyor-type transport systems are described by the same system of equations (27) – (29) and, under the same initial conditions, have the same solution.

VI. ANALYSIS OF THE RESULTS

When constructing similarity criteria characterizing the process of material transportation in a belt conveyor, the main factors determining the studied parameters of the system are identified. To construct a table of the main parameters of the system, a system of equations for modelling the process of material transportation in a transport conveyor (1) - (3) is used. It is possible to approach the formation of a table of the main factors (determinant parameters) describing the process of material transportation without using analytical equations of the model, having established those factors that are necessary for a complete determination of the characteristics of the process of material transportation, the numerical values of the parameters of which are measured as a result of the experiment. In this case, when compiling a system of determining parameters of the model, it is necessary to schematize the transportation process. In contrast to this, the approach based on the system of equations significantly simplified this process and made it possible to schematize, construct and substantiate equations for modelling the process of material transportation in dimensionless form. Among the determining parameters of the system, the main parameters of the system are highlighted. Through these main parameters of the system, the determining parameters are expressed

In the approach proposed in this article, the Dirac function $\delta(S)$ is considered in the qualitative analysis as a separate value in equation (1), because it plays a special role, models a point source of material inflow, and provides an idealized representation of a local source of material inflow into the conveyor. The similarity criterion obtained on its basis establishes a geometric relationship of the point for material inflow into the transport system. In the general case, the similarity criterion has the form $\pi_3 = S_d\delta(S - S_k)$, which is determined by equation (4). However, to simplify the method for constructing similarity criteria for a transport system, it is assumed that the material enters the conveyor input with point $S_0 = 0$, $\pi_3 = S_d\delta(S - S_0)$. If there are several points of material inflow, then to ensure geometric similarity, it is necessary to add similarity criteria for each local source of material inflow.

As was indicated earlier, each studied process of material transportation can be characterized by certain parameters, for example, for a model with a deterministic input flow of material $\chi_0^*, \chi_1^*, \lambda^*, t^*, S^*$. Having characteristic values of these quantities, the value for a specific similarity criterion can be calculated, which allows us to answer whether the transportation processes in two different conveyors are similar. Characteristic quantities are usually different for each studied transportation process. For example, for the same conveyor there may be cases of material transportation in which the conveyor belt loading differs significantly, for example $\chi_{01}^* >> \chi_{02}^*$. Then these two transportation processes will be described by equations (16) – (18) with different values of the parameter and, what is important, for comparing dimensionless values of densities it is necessary to introduce an additional scaling factor that determines the relationships between the characteristic values of densities χ_{01}^*, χ_{02}^*. In this regard, after solving the problem that requires an answer to whether two conveyors are similar, it is more convenient to move on to another set of quantities that determines the dimensionless parameters of the model when analysing the systems of equations (1) – (3).

Among such quantities it is necessary to specify: S_d – the length of the conveyor; $\chi_{0\max}$ – the maximum permissible linear density of the material at which there is no spillage of the material; T_d – the characteristic time of the process. The last quantity requires special attention. This can be the time interval during which the material on average passes the entire transportation path of length S_d (for the model with a deterministic input material flow) or the time interval equal to the correlation time η_d of the stochastic input process (for the model with a stochastic input material flow), at which the value of the correlation function decreases by $e \approx 2.718 = k(0)/k(\eta_d)$ times, where $k(\eta)$ is the correlation function of the stochastic process describing the arrival of the input material flow at the entrance of the transport conveyor. Replacing $\chi_0^* \to \chi_{0\max}$, $\chi_1^* \to \chi_{0\max}\dfrac{S_d}{T_d}$, $\lambda^* \to \chi_{0\max}\dfrac{S_d}{T_d}$, $t^* \to T_d$, $S^* \to S_d$ and using the new parameters for constructing dimensionless quantities:

$$\tau = \frac{t}{T_d},\ \xi = \frac{S}{S_d},\ \Theta_0 = \frac{\chi_0}{\chi_{0\max}},\ \delta(\xi) = S_d\delta(S), \quad (30)$$

$$g(\tau) = a(t)\frac{T_d}{S_d},\ \Theta_1 = \frac{\chi_1}{\chi_{0\max}\dfrac{S_d}{T_d}},\ \gamma = \frac{\lambda}{\chi_{0\max}\dfrac{S_d}{T_d}}. \quad (31)$$

let us rewrite the system of equations for the model with a deterministic input flow of material (1) – (3) in dimensionless form:

$$\frac{\partial\Theta_0(\tau,\xi)}{\partial\tau} + \frac{\partial\Theta_1(\tau,\xi)}{\partial\xi} = \delta(\xi)\gamma(\tau), \quad (32)$$

$$\Theta_1(\tau,\xi) = g(\tau)\Theta_0(\tau,\xi),\ \ \Theta_0(0,\xi) = H(\xi)\psi(\xi), \quad (33)$$

For the case of a constant belt speed $a(t) = a_d$ with a given choice of T_d as the time interval during which the material on average passes the entire transport path of length S_d, follows $a_d = S_d/T_d$, and accordingly the scale for the value $g(\tau) \sim 1$. It should also be noted that the ratio $\chi_0/\chi_{0\max} = (\chi_0 S_d)/M_{\max}$ can be interpreted as the material loading coefficient of the transport system, which is important for the analysis of the energy characteristics of the transport system. The value $M_{\max} = \chi_{0\max}S_d$ is the maximum possible mass of material that can be placed on the conveyor belt. It should also be noted that the ratios:

$$\frac{\chi_1}{\chi_{0\max}\dfrac{S_d}{T_d}} = \frac{\chi_1 T_d}{M_{\max}},\ \ \frac{\lambda}{\chi_{0\max}\dfrac{S_d}{T_d}} = \frac{\lambda T_d}{M_{\max}}, \quad (34)$$

They also have a scale characterized by the material loading coefficient of the transport conveyor. The new dimensionless parameters introduced allow us to conveniently analyse the behaviour of the conveyor flow parameters under different material transportation conditions. Let us perform a similar analysis for a model with a stochastic input material flow. When analysing the systems of equations (1) – (3), when the similarity criteria of the transport systems have already been determined, we move on to the following set of values that determine the dimensionless parameters of the model: S_d – conveyor length; $\chi_{0\max}$ – maximum permissible linear density of the material at which there is no material spillage; η_d – correlation time of the stochastic input process characterizing the input material flow. Having performed the following replacement of the characterizing parameters, $\chi_0^* \to \chi_{0\max}$, $\chi_1^* \to \chi_{0\max}\dfrac{S_d}{\eta_d}$, $m_\lambda^* \to \chi_{0\max}\dfrac{S_d}{\eta_d}$, $\sigma_\lambda^* \to \chi_{0\max}\dfrac{S_d}{\eta_d}$, $\eta^* \to \eta_d$ $t^* \to \eta_d$, $S^* \to S_d$ and using the new parameters to construct dimensionless quantities:

$$\tau = \frac{t}{\eta_d},\ \xi = \frac{S}{S_d},\ \Theta_0 = \frac{\chi_0}{\chi_{0\max}},\ \delta(\xi) = S_d\delta(S), \quad (35)$$

$$g(\tau) = a(t)\frac{\eta_d}{S_d}, \qquad \Theta_1 = \frac{\chi_1}{\chi_{0\max}\dfrac{S_d}{\eta_d}}, \tag{36}$$

$$m_\gamma = \frac{m_\lambda}{\chi_{0\max}\dfrac{S_d}{\eta_d}}, \ \sigma_\gamma = \frac{\sigma_\lambda}{\chi_{0\max}\dfrac{S_d}{\eta_d}}. \tag{37}$$

let us rewrite the system of equations for the model with a stochastic input flow of material (1) – (3) in dimensionless form:

$$\frac{\partial\Theta_0(\tau,\xi)}{\partial\tau}+\frac{\partial\Theta_1(\tau,\xi)}{\partial\xi} = \delta(\xi)m_\gamma\left(1+\frac{\sigma_\gamma}{m_\gamma}\gamma(\tau)\right). \tag{38}$$

$$\Theta_1(\tau,\xi) = g(\tau)\Theta_0(\tau,\xi), \quad \Theta_0(0,\xi) = H(\xi)\psi(\xi). \tag{39}$$

Just as in the model for a deterministic input flow of material for the case of a constant belt speed $a(t) = a_d$, we obtain $a_d = S_d / T_d = (S_d / \eta_d)k_g$, where k_g is the scaling factor for the dimensionless belt speed: $g(\tau) \sim k_g$. Just as before, parameters Θ_0, Θ_1, m_γ characterize the material loading factor of the transport conveyor.

VII. Conclusion

In this paper, we consider methods for modelling material transportation processes in conveyor systems using dimensionless parameters based on the principles of similarity theory. The construction and analysis of similarity criteria made it possible to identify the key physical parameters that have the greatest impact on the behaviour of the transport system under both deterministic and stochastic input material flows.

The use of the π-theorem made it possible to obtain a system of dimensionless equations that adequately describe the behaviour of the flow characteristics of the system under various operating modes. The criteria are determined under which transport systems are described by the same system of equations and, therefore, can be considered as similar systems. This opens up the possibility of transferring experimental data and modelling results from one system to another, which is especially important when designing new energy-saving control systems.

The proposed approach can be effectively used in planning and interpreting experimental studies, as well as in developing control algorithms for conveyor transport systems. Further research can be aimed at taking into account nonlinear effects, interactions between several flows, and integrating the obtained models into intelligent control systems.

***Abstract*—The paper deals with researching the possibilities of the robust control of electric servo drives assigned for the stabilization of the payload mounted on mobile objects. The mathematical description of the electric servo drive is represented. The features of the description for electric drives assigned to land mobile objects are explained. In the model, disturbance moments inherent in electric drives of land mobile objects are taken into consideration. The Simulink model of the electric motor has been developed. The theoretical grounds of the robust structural synthesis are given. The basic principles of robust control inherent in electric drives of land-mobile objects are described. The equations for determining the output signals of the studied system are represented. A robust structural synthesis has been implemented for the electric servo drive used on a land mobile object. The results of modeling the synthesized system are shown and analyzed. The transient processes in such modes as tracking and stabilization are given. The determination of the angular rigidity of the platform with payload by simulation is proposed. The obtained results can be useful for the synthesis of systems for controlling electric drives assigned for operation on mobile objects of a wide class.**

Keywords—electric servo drive, robust structural synthesis, mathematical description, modeling, discrete control unit

I. Introduction

Control of servo drives based on a DC motor is relevant for many industrial areas. Studying gyroscopic two-mass servo systems is particularly interesting for these drives. Such systems ensure stabilization and tracking of the payload, for example, a movie camera installed on a mobile land object, and a stabilization and guidance system for a radar antenna installed in rotating gimbals [1], [2].

The widespread approach to developing control systems is the application of robust control. The robust systems are insensitive to both the variation of system parameters and the influence of external disturbances [3]. This gives great possibilities for the operation of electric servo drives, which are used for control and stabilization systems assigned for mobile objects of different types (land, marine, and aerial).

The synthesis of robust systems can be based on minimizing the H_{inf} norm of the matrix transfer function of a closed-loop system. There is also a known approach to system synthesis based on minimizing the H_2 norm of the matrix transfer function of a closed-loop system. It is worth mentioning that, from the point of view of implementing computational algorithms, H_{inf} optimization is much more complicated than H_2 optimization due to the need to implement a search procedure. Synthesis methods based on minimizing the H_2 norm provide high accuracy of the synthesized system, but they remain sensitive to both external disturbances and parametric disturbances of the control object. The use of the H_{inf} norm allows ensuring the system's resistance to external disturbances under the condition of structured and unstructured parametric uncertainties [3], [4]. Optimization according to each of the considered approaches has definite advantages. The optimization according to a mixed criterion allows combining these advantages [5]. In such a situation, the synthesized system will be characterized by optimal quality in the presence of disturbances. The features of creating robust stabilization systems, using H_2, H_{inf}, and mixed H_2/H_{inf} approaches, and their comparative analysis are presented in [3], [6].

II. Analysis of Last Research

Methods for creating servo systems with a DC motor are described in sufficient detail in [7] – [9]. The issues of mathematical modeling of systems of the considered type are described in [5], [6], [10]. However, while many approaches to mathematical modeling of systems under consideration have remained relevant nowadays, computer modeling methods have changed significantly due to new computing tools. Therefore, it is important to study the possibilities of modeling servo drive devices, taking into account the development of modern computing technology. In addition, the development of a methodology for the transition from a continuous control system to a digital one is of great interest for the design of modern servo systems. The availability of such a methodology allows, on the one hand, to apply the useful results of previous developments, and on the other hand, to create servo systems that meet the modern requirements. Finally, it will be observed that lies in the relevance of creating models of electronic devices that allow choosing the discreteness of information updates, since the solution to this issue largely determines the ways of creating the system as a whole.

A large number of scientific publications are dedicated to the creation of robust control systems. The main principles that led to the development of the robustness theory are based on the Kharitonov theorem [3]. There are three main directions for the development of the robustness theory. The first approach is based on the concept of a multi-dimensional stability limit. Another approach is based on the idea of a structured singular value. The third approach is related to applying linear matrix inequalities [3], [11].

One of the central ideas underlying the robustness analysis method comes from understanding the Nyquist criterion, on which the theorem about the small gain coefficient is based [3]. Relevant problems in the synthesis of robust control systems are given in many publications, for example, [12]. Features of the design of robust stabilization systems, and their characteristics analysis are presented in [5], [6], [13].

Algorithms for parametric and parametric-structural synthesis of robust systems assigned for the stabilization of payload mounted on land mobile objects are represented in [14]. The development of appropriate procedures for structural synthesis of stabilization systems for land mobile objects remains an urgent problem.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

The creation of methods for synthesizing a stochastic system requires taking into account specific external disturbances acting on the system of the type under study. For land mobile systems, external disturbances are caused by road and terrain irregularities. To date, deterministic and statistical approaches are known that allow us to take into account disturbances acting on a land mobile object with payload In the first approach, the profile of road irregularities is described by a predetermined, most often harmonic function. In the statistical approach, disturbances caused by road irregularities are considered random variables. Taking into account random disturbances allows the creation of procedures for synthesizing a stochastic system of the class under study.

III. Description of Electric Servo Drive

The electric servo drives for a stabilization and tracking system assigned for operation on a land mobile object should provide stabilization and tracking of a payload in the vertical and horizontal planes. Electronic device models of the vertical and horizontal channels differ only in some components, as well as their parameters. Therefore, in this paper, the emphasis is placed on the mathematical description of the electric servo drive for the vertical channel [16], [17].

Following [16], the electric servo drive for the stabilization and tracking system assigned for land mobile objects includes series-connected units such as a motor, a reducer, and a voltage amplifier. The drive control signals are formed in the pulse-width modulator based on the signals coming from the control unit of the stabilization and tracking system. The control in the vertical plane is grounded on signals of the gyroscopic tachometer, the control panel, and feedback signals of the electric motor current and voltage. The functions of the electronic devices of the vertical channel of the tracking system include amplification, filtering, integration, and the formation of control laws. A special feature of the vertical channel model is the presence of limiting devices and switches, since in some situations, the type of electronic device model depends on the signal level. The control unit also performs the reduction to a single dimension of the current and voltage feedback signals. The functions of the electronic devices of the horizontal channel of the tracking system include integration, implementation of high- and low-frequency filters, band-pass filters, formation of control laws, and reduction to a single dimension of the voltage and current signals.

The output signal of the control unit enters the pulse-width-modulator model, in which a sequence of pulses of a given voltage. The width of pulses varies and depends on the control signal. This sequence is the input value for the electric motor model. In turn, the motor model includes a relationship for forming the motor armature current, an aperiodic link that takes into account the armature and the electromechanical time constants, and a model of the mechanical part of the motor. The motor armature current is used to form the drive control torque, as well as voltage and current feedback signals. The voltage on the motor circuit winding is determined in the following way

$$U_{win} = U_{pwm} - c_{emf}\dot{\varphi}_m, \tag{1}$$

where U_{win} is the voltage in windings of the motor armature, U_{pwm} is the voltage on the output of the pulse-width-modulator, c_{emf} is the electromotive force; φ_m is an angle of the turn of the motor.

The time constant of the motor armature circuit is taken into account through an aperiodic unit with a gain:

$$T_a pU_{cor} + U_{cor} = U_{win}, \tag{2}$$

where T_a is the motor armature circuit time constant, U_{cor} is the corrected output signal of the aperiodic unit. The signal U_{cor} enters the voltage feedback circuit, then through the unit $\frac{1}{R_{win}}$ into the current feedback circuit (J_{cor}) and then through the load torque constant on the motor shaft c_m to the mechanical part of the electric motor. Thus, the motor control torque is formed using the relationship $M_m = c_m J_{cor}$.

The mathematical model of the mechanical part of the motor is the following differential equation:

$$J_m\ddot{\varphi}_m + M_{res}\operatorname{sign}\dot{\varphi}_m = M_{con} - c_g\frac{\varphi_{hys} - \varphi_{pl}n_g}{n_g^2}, \tag{3}$$

where M_{con} is the motor control torque; M_{res} is the torque of resistance to rotation; is the gearbox rigidity; n_g is the gearbox ratio; J_m is the motor moment of inertia; φ_m is the motor rotor rotation angle; φ_{hys} is the motor rotor rotation angle taking into account the hysteresis-type nonlinearity caused by the motor backlash; φ_{pl} is the rotation angle of the payload.

The expressions (1) – (3) describe the mathematical models of basic units of the electric servo drive assigned for the stabilization and tracking of a payload mounted on the mobile object.

The features of the mathematical model of the electric servo drive with DC motor include the following factors:

- Presence of the hysteresis-type nonlinearity, for this, the rotation angle of the motor rotor (the output signal of the mathematical model of the engine) is passed through a nonlinear link.
- The relationship between the mechanical part of the motor and the working unit is implemented through the gearbox. Mathematically, this relationship is ensured by introducing the rotation angle of the working unit into equation (3). In this case, the rotor and the working unit represent a single device for reproducing the control signal (the so-called two-mass system).

To establish the adequacy of the model to real motor operation, zeroing of the motor rotation acceleration at the zero speed, and the fulfillment of certain relationships between the moments acting on the motor are introduced. These conditions are as follows:

$$\left|M_m - c_g\frac{\varphi_{hys} - \varphi_{pl}n_g}{n_g^2}\right| \le |M_{res}|; \quad \dot{\varphi}_m = 0. \tag{4}$$

The relationship between the payload and the motor can be described using the following equation:

$$J_{pl}\ddot{\varphi}_{pl} + M_{fr}\operatorname{sign}\dot{\varphi}_{fr} - M_{unb}\sin\varphi_{unb} + k_{spr}\varphi_{pl} + c_g\varphi_{pl} = k_{spr}A + c_g\varphi_{hys}/n_g - M_{unb}, \tag{5}$$

where M_{fr} is the friction moment; M_{unb} is the moment of unbalance; k_{spr} is the spring stiffness; A is the lifting angle of

the balancing spring; J_{pl} is the moment of inertia of the payload; φ_{pl} is the angle of rotation of the payload.

The expressions (4), and (5) represent the basic equation of the electric servo drive, taking into consideration conditions that close the model to real operation.

IV. Control of Electric Servo Drive

The control of the electric servo drive is based on the robust structural synthesis when both the structure and parameters are defined. The most appropriate is to use H_{inf} synthesis, that is, multi-criteria robust structural synthesis, which ensures system design under uncertainty [3[, [19], [20].

In the general form, the control system looks like

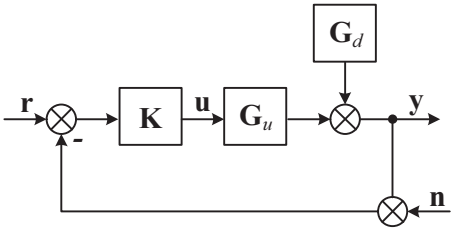

Fig. 1. The block diagram of the control system.

For this system, equations for determining output signals **y**, control **u** and error **e** can be determined using transfer functions of the control object $\mathbf{G}_u$, disturbance $\mathbf{G}_d$ and regulator **K**, and also input signals such as a reference signal **r**, disturbance **d**, and measurement error **n** [3], [13]

$$\begin{aligned} \mathrm{y} &= \mathrm{G}_u\mathrm{K}(\mathrm{I}+\mathrm{G}_u\mathrm{K})^{-1}\mathrm{r}+(\mathrm{I}+\mathrm{G}_u\mathrm{K})^{-1}\mathrm{G}_d\mathrm{d}- \\ &\mathrm{G}_u\mathrm{K}(\mathrm{I}+\mathrm{G}_u\mathrm{K})^{-1}\mathrm{n}; \\ \mathrm{u} &= \mathrm{K}(\mathrm{I}+\mathrm{G}_u\mathrm{K})^{-1}\mathrm{r}-\ \mathrm{K}(\mathrm{I}+\mathrm{G}_u\mathrm{K})^{-1}\mathrm{G}_d\mathrm{d}- \\ &\mathrm{K}(\mathrm{I}+\mathrm{G}_u\mathrm{K})^{-1}\mathrm{n}; \\ \mathrm{e} &= (\mathrm{I}+\mathrm{G}_u\mathrm{K})^{-1}\mathrm{r}-\ (\mathrm{I}+\mathrm{G}_u\mathrm{K})^{-1}\mathrm{d}-(\mathrm{I}+\mathrm{G}_u\mathrm{K})^{-1}\mathrm{n}\,. \end{aligned} \tag{6}$$

Using equations (6), it may be possible to estimate the system characteristics. Matrix transfer functions from the command signal **r** to the error, control, and output signals **e**, **u**, **y** are defined as follows

$$\begin{aligned} \mathrm{S}(j\omega) &\overset{\text{def}}{=} (\mathrm{I}+\mathrm{G}_u(j\omega)\mathrm{K}(j\omega))^{-1}; \\ \mathrm{R}(j\omega) &\overset{\text{def}}{=} \mathrm{K}(j\omega)(\mathrm{I}+\mathrm{G}_u(j\omega)\mathrm{K}(j\omega))^{-1}; \\ \mathrm{T}(j\omega) &\overset{\text{def}}{=} \mathrm{G}_u(j\omega)\mathrm{K}(j\omega)(\mathrm{I}+\mathrm{G}_u(j\omega)\mathrm{K}(j\omega))^{-1}. \end{aligned} \tag{7}$$

In expressions (7), the matrix transfer function from the reference signal **r** to the error signal **e** is called the sensitivity function $\mathbf{S}(j\omega)$. The matrix transfer function $\mathbf{T}(j\omega)$ from the control reference signal **r** to the output signal **y** is called the complementary sensitivity function. The matrix transfer function $\mathbf{R}(j\omega)$ from the reference signal **r** to the control signal **u** is called the control sensitivity function.

The simultaneous use of these three sensitivity functions allows you to achieve a compromise between accuracy, robustness, and control costs.

It will be noticed that all the above requirements are mutually contradictory and cannot be satisfied simultaneously. In this case, the search for the optimal regulator is carried out on a set of regulators that ensure the internal stability of the system. This approach is the most common in H_{inf} synthesis procedures. Such an approach is used in the mixed sensitivity method. The expression for the optimization criterion and, accordingly, the formulation of the optimization problem for the mixed sensitivity method are

$$\mathbf{K}_{opt} = \arg \inf_{\mathbf{K}_{opt}\in\mathbf{K}_{per}} J(\mathbf{G},\mathbf{K}), \tag{8}$$

$$J(\mathrm{G},\mathrm{K}) = \left\| \begin{bmatrix} (\mathrm{I}+\mathrm{GK})^{-1} \\ \mathrm{K}(\mathrm{I}+\mathrm{GK})^{-1} \\ \mathrm{GK}(\mathrm{I}+\mathrm{GK})^{-1} \end{bmatrix} \right\|_{\infty}. \tag{9}$$

To formulate the problem of H_{inf} synthesis (8), (9), it may be to use a formalized representation. The appropriate block diagram is represented in Fig. 2. [3]

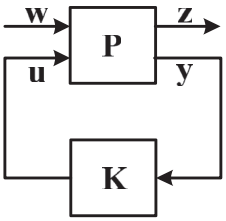

Fig. 2. The problem statement of H_{inf} synthesis.

The synthesized system is described as a control object (together with a measuring system and an actuator) and a regulator with matrix transfer functions $\mathbf{P}(s)$, $\mathbf{K}(s)$, which are fractional-rational and regular. The control object is a system with two inputs **w**, **u,** and outputs **z**, **y**. The input vector **w** in the generalized representation includes disturbances, measurement interference, and command signals. The input vector **u** describes control signals. The output vector ***z*** can be used for estimating the quality of stabilization and tracking processes; for example, it can represent the tracking error of the reference signal. The output vector **y** describes a vector of observed signals that can be used to organize feedback [21] – [23]. The control system shown in Fig. 2 can be described in the state space as follows:

$$\begin{aligned} \dot{\mathrm{x}}(t) &= \mathrm{A}\mathrm{x}(t)+\mathrm{B}_1\mathrm{w}(t)+\mathrm{B}_2\mathrm{u}(t); \\ \mathrm{z}(t) &= \mathrm{C}_1\mathrm{x}(t)+\mathrm{D}_{11}\mathrm{w}(t)+\mathrm{D}_{12}\mathrm{u}(t); \\ \mathrm{y}(t) &= \mathrm{C}_2\mathrm{x}(t)+\mathrm{D}_{21}\mathrm{w}(t)+\mathrm{D}_{22}\mathrm{u}(t); \\ \mathrm{u}(t) &= \mathrm{K}\mathrm{y}(t). \end{aligned} \tag{10}$$

The mathematical model (10) can be represented in the following form [3], [13]:

$$\begin{bmatrix} \dot{\mathrm{x}}(t) \\ \mathrm{z}(t) \\ \mathrm{y}(t) \end{bmatrix} = \begin{bmatrix} \mathrm{A} & \mathrm{B}_1 & \mathrm{B}_2 \\ \mathrm{C}_1 & \mathrm{D}_{11} & \mathrm{D}_{12} \\ \mathrm{C}_2 & \mathrm{D}_{21} & \mathrm{D}_{22} \end{bmatrix} \begin{bmatrix} \mathrm{x}(t) \\ \mathrm{w}(t) \\ \mathrm{u}(t) \end{bmatrix}. \tag{11}$$

If to write the transfer function of the control object as

$$\mathrm{P} = \begin{bmatrix} \mathrm{P}_{11} & \mathrm{P}_{12} \\ \mathrm{P}_{21} & \mathrm{P}_{22} \end{bmatrix}, \tag{12}$$

we can obtain the transfer function of the closed-loop system from input w to output z [3]:

$$T_w^z = P_{11} + P_{12}K(I - P_{22}K)^{-1}P_{21} \quad T_w^z = P_{11} + P_{12}K(I - P_{22}K)^{-1}P_{21} \tag{13}$$

H_{inf} synthesis allows us to determine the robust regulator K(s), which minimizes the norm $\| T_w^z \|_\infty$ of the closed-loop control system, where [3]

$$T_w^z = \begin{bmatrix} (I + GK)^{-1} \\ K(I + GK)^{-1} \\ GK(I + GK)^{-1} \end{bmatrix} = \begin{bmatrix} S \\ R \\ T \end{bmatrix}. \tag{14}$$

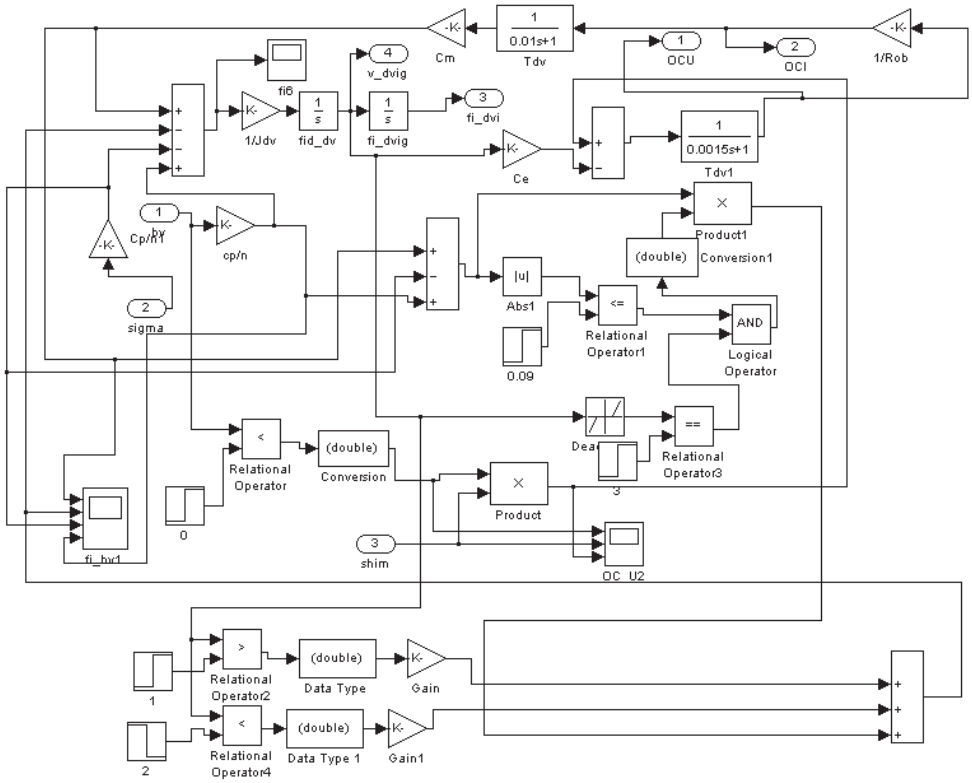
V. Computer Modelling of Electric Servo Drive

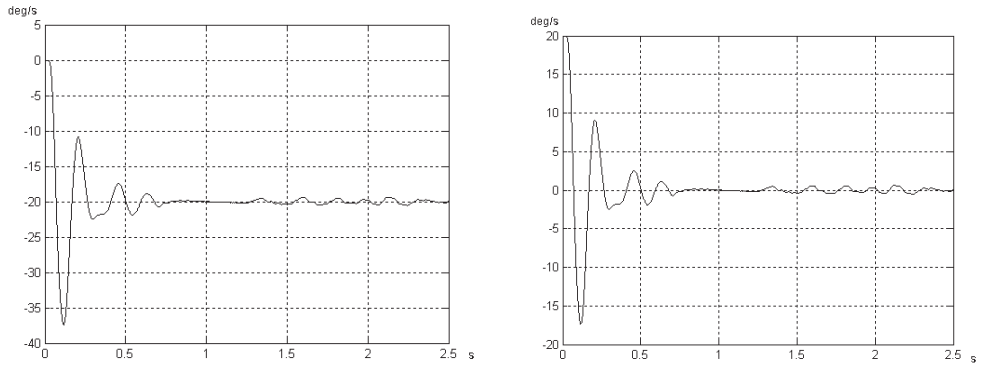
After realizing the optimization algorithm (11) – (14), the computer modelling of the synthesized system has been done. The model of the servo drive is realized in the Simulink Toolbox of the MATLAB system [24], [25]. It is based on transfer functions of the servo drive units.

The application of the Simulink model allows one to take into account nonlinear units and bring the model closer to the real hardware implementation.

As an example, the computational scheme of the motor is given in Fig. 3.

Other Simulink models are not given for the simplicity of the paper presentation. Simulation results are given in Figs. 4, 5.





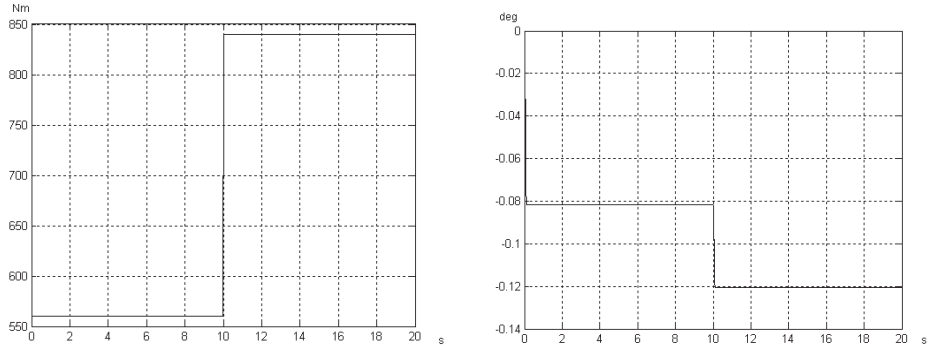


Fig. 3. Simulink model of the motor.

a *b*

Fig. 4. Transient processes on the angular rate: a – tracking the given angular rate; b – stabilization process.

c *d*

Fig. 5. The determination of the angular rigidity of the stabilized platform with a payload: a – tested disturbing moment; b – reaction of the angular position of the stabilized platform.

Figs 4a and 4b show the transient processes for the relative and absolute velocity for the vertical discrete channel. The imitation of the object body motion in the vertical plane was set using the transfer velocity. As follows from the simulation results, when the object moves at a speed of 20 deg/s, the deviation of the absolute velocity relative to the zero level does not exceed the permissible level.

Figs 5a and 5b confirm the required angular rigidity of the system. For this, the absolute angles of rotation of the working unit are analyzed after the action of forces of 560 Nm and 840 Nm, respectively.

The H_{inf} norm of the synthesized system is 0.1248. This value proves high robustness. At the same time, the accuracy of the system is sufficient as it is characterized by H_2 norm equal to 0.3653.

Analysis of logarithmic amplitude-frequency characteristics has shown that margins on the amplitude and phase are 49.5 dB and 91.1 degrees, respectively.

VI. Transition from Continuous Control Unit to Discrete One

Modern servo drives involve the use of computing tools. Therefore, developing a method for the transition from a continuous control unit to a digital one is of considerable interest. For this purpose, it is proposed to create a model of a continuous control channel using a transfer function apparatus, for example, using known analytical dependencies. This process is quite complex, and the correctness of the analytical representation should be verified by conducting appropriate experiments on a test bench.

In addition, it is advisable to use modern systems for modeling electronic devices, WorkBench or MultiSIM, which allow determining the logarithmic amplitude-frequency characteristics of separate transfer functions. These characteristics should be compared with similar characteristics of analytical transfer functions, for example, using the MATLAB system [26], [27].

Unfortunately, the WorkBench system does not have the ability to directly determine the analytical representation of the transfer function based on the model of an electronic device. It is worth mention that such a possibility exists in the MATLAB system, but for a subsystem designed for modeling power energy circuits, which is associated with certain difficulties in modeling electronic devices.

After representing a continuous control block in the form of a model using transfer functions, a transition to a digital block is carried out using Z-transformation of the corresponding transfer functions by program methods. To realize this approach, you can use the Control Toolbox of the MATLAB system, namely the c2d function.

The choice of the discretization method is determined by the required accuracy of the transformation, which is estimated by the degree of coincidence of the logarithmic amplitude-frequency characteristics of the transfer functions with similar characteristics of the continuous transfer functions.

It will be observed that the transfer function of the digital integrator is most sensitive to the discretization method. Therefore, it is advisable to use a sufficiently accurate bipolar transformation.

The advantages of the proposed approach to modeling electronic control devices for a servo drive include the possibility of studying the permissible value of the discreteness of information processing, the possibility of introducing tuning coefficients into the model, and the use of a pulse-width modulator model. When selecting the discreteness interval, the problem of ensuring a compromise between the desired accuracy and the convenience of hardware implementation of the control unit is solved [28], [29].

Tuning coefficients are provided to improve the quality of control processes based on the results of modeling and testing [17]. Such indicators as the duration of the transient process, the number of overruns, and the required rigidity of the system are taken into account.

The pulse-width modulator model can be described in detail using the Simulink system. In addition, the presented model provides the ability to select the discreteness of the analog-digital conversion, since it allows analyzing the frequency characteristics of the output signals of separate units.

Specific problems related to astatism for a discrete system are solved by finding the minimum implementation, similarly to the continuous system. As for the balanced implementation, it can be realized for continuous systems. In the case of a discrete system, it is advisable to perform scaling of the model

matrices in the state space using a similarity transformation with a diagonal matrix and a scalar coefficient [30].

VII. Conclusions

The mathematical model of the servo drive is represented, including the description of the motor armature circuit, the mechanical part of the motor, and the condition of the mathematical modelling proximity to real operation. Modeling of the synthesized system was implemented by Simulink Toolbox.

The features of the robust structural synthesis based on H_{inf} norm are described. The optimization problem and objective function based on the method of mixed sensitivity are represented.

The robust structural synthesis of the system with the electric servo drive assigned for stabilization and tracking a payload mounted on a land mobile object has been discussed. The results of the robust structural synthesis, including transient processes on the angular rate, checking angular rigidity, and calculation of H_{inf} and H_2 norms are represented. The obtained results prove the high robustness and accuracy of the synthesized system.

The represented procedure of the robust structural synthesis can be applied to mobile objects of another type.

The approach to the transformation of the continuous control unit into a discrete one is described. The proposed approach is based on modern specialized software assigned for researching complex engineering systems of a different kind.

***Abstract*— The article presents a comprehensive spatial-analytical study of the potential for the development of renewable energy sources (RES) across the territory of Ukraine, taking into account the geographical distribution of end electricity consumers. The primary focus is on identifying priority regions for the deployment of renewable energy infrastructure, where high resource and energy potential coincides with optimal energy supply logistics.The methodological framework of the study is based on the integration of geoinformation analysis, cartographic modeling, and techno-economic energy assessment. The spatial data analysis has enabled not only the localization of promising renewable energy accumulation zones, but also an evaluation of the impact of consumer geographic remoteness on energy transmission losses and overall system efficiency. The modeling results open new horizons for strategic energy planning, highlighting the necessity of aligning the placement of RES facilities with the spatial structure of energy demand. A series of practical scenarios are proposed, aimed at minimizing transmission losses while simultaneously increasing national-level energy efficiency. The findings carry applied significance for government regulators, institutional investors, and expert communities involved in the transformation of Ukraine's energy landscape toward sustainable development.**

Keywords*— *geoinformation analysis, renewable energy potential, spatial modeling, electricity consumers distribution.

I. INTRODUCTION

In the modern era of global challenges and civilizational shifts, the issue of energy transformation ceases to be just a technical or environmental dilemma. It acquires a strategic, even existential dimension. In a country experiencing tectonic socio-economic transformations, aggressive external threats and deep internal restructuring, energy is becoming the sphere where the vectors of national security, technological breakthrough and geopolitical subjectivity intersect. Ukraine today faces a unique historical opportunity - to create a new model of the energy ecosystem, which will be based not on the inertia of the past, but on an accurate, scientifically substantiated idea of space, resources and needs of society. The essence of this scientific work is to form an innovative paradigm of a spatial-analytical approach to assessing and modeling the potential of renewable energy within the territory of Ukraine. We are not limited to a quantitative analysis of opportunities - how much sun, wind or biomass is in a particular area - we offer a deep synergy between physical geography, spatial logic of infrastructure placement and real energy needs of the population and industry. At the heart of our approach is the idea of precisely matching the generation potential with the location of consumers, which allows not only to use resources more efficiently, but also to reduce losses, optimize distribution and increase the overall stability of the energy system.

In this context, space ceases to be just a physical background - it turns into a data carrier, a key indicator and a strategic factor in energy planning. Our modeling is based on the use of high-precision geo-information analytics, satellite monitoring, mathematical optimization algorithms and multi-level scenario approaches. At the heart is the idea that every square kilometer of Ukrainian land contains a unique energy formula, and the task of science is to reveal, digitize and make this formula manageable.

This work is a contribution to the formation of a new type of national thinking - energy-spatial, flexible, long-term thinking. We are not just mapping renewable energy - we are creating a new mental landscape in which decisions are made not at random, but on the basis of precise spatial-energy relationships. It is this approach that gives Ukraine a chance not only for energy independence, but also for Ukraine to enter the vanguard of the global green transition. Spatial-analytical thinking is the intellectual key to a new energy civilization, which we are starting to build right now.

II. REVIEW OF SCIENTIFIC SOURCES

The issue of renewable energy has long attracted the attention of scientists, engineers, and policymakers, as it represents not only a technological challenge but also a strategic necessity for humanity's sustainable future. Research in this field is vast and diverse, encompassing technical, economic, and ecological perspectives. When analyzing the state of scientific knowledge, it becomes clear

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

that renewable energy is not studied as an isolated discipline but rather as an integral part of global energy transformation, in which solar, wind, hydro, biomass, and geothermal energy gradually replace fossil fuel–based generation. Scholars consistently emphasize that this process is not linear; instead, it requires the synthesis of advanced technologies, infrastructure adaptation, and active regulation from governments.

One of the central themes in the literature is the steady advancement of solar photovoltaic (PV) systems. Numerous studies demonstrate that the cost of PV modules has dramatically decreased over the past two decades due to technological breakthroughs, economies of scale, and improvements in manufacturing processes [1]. At the same time, researchers highlight the challenges of intermittency, efficiency fluctuations under changing weather conditions, and the urgent need for energy storage solutions. The development of high-capacity lithium-ion and emerging solid-state batteries is frequently presented as a decisive factor for the large-scale integration of solar power into national grids [2].

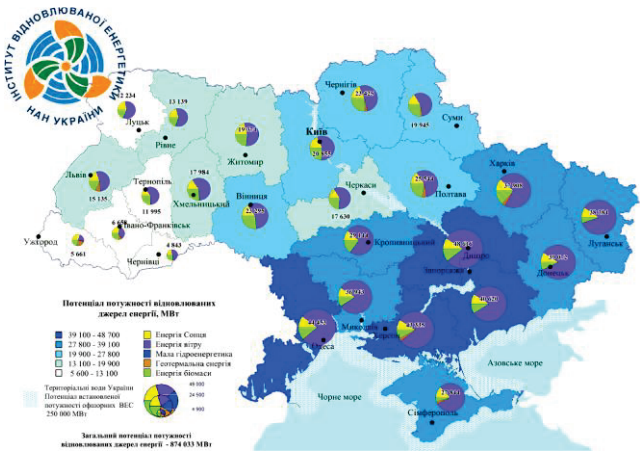
Equally significant attention is given to wind energy, which is considered one of the most promising renewable sources due to its scalability and relatively mature technology. Scholars analyze both onshore and offshore wind farms, noting that offshore installations are capable of providing higher and more stable energy outputs but require substantial capital investments and advanced grid connections [3]. Technical reviews often point to innovations in turbine design, the use of composite materials, and digital monitoring systems that extend the operational life of wind turbines and reduce maintenance costs [4].

Beyond the technical dimension, researchers stress the socio-economic and political aspects of renewable energy deployment. For instance, the transition to clean energy is frequently described as a catalyst for regional development, job creation, and innovation stimulation. However, literature also identifies barriers such as high initial capital costs, policy uncertainty, and social resistance in certain communities [5]. Particularly in developing countries, scholars underline the necessity of stable regulatory frameworks and international cooperation to attract investments and ensure long-term sustainability [6].

Another important body of work focuses on hybrid renewable energy systems, which combine different sources such as solar and wind with storage technologies to ensure reliability and efficiency. According to recent studies, such hybrid models are becoming increasingly popular in both urban and rural contexts, as they mitigate the weaknesses of individual sources and provide continuous power supply [7]. For instance, microgrid systems in remote regions have shown remarkable potential in providing decentralized energy access, reducing dependence on fossil fuels, and improving resilience against climate-related risks [8].

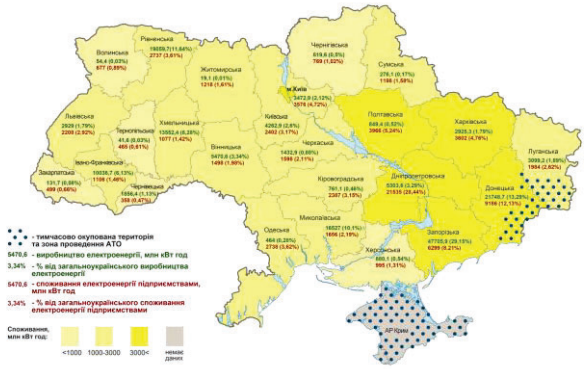
A critical line of inquiry concerns environmental and ecological implications. While renewable energy is often portrayed as environmentally friendly, researchers note that large-scale implementation must account for land use, resource extraction for batteries, and potential impacts on ecosystems. Wind farms may influence bird migration patterns, while solar installations require significant land resources if not integrated into rooftops or existing infrastructures. These issues underscore the importance of life-cycle assessments and holistic approaches to planning renewable energy projects [9-13].

III. OUTLINE OF THE MAIN MATERIAL



The methodology underpinning this study is based on a combination of geospatial analysis, computational modeling, and techno-economic assessment to evaluate the renewable energy potential of Ukraine while taking into account the spatial distribution of electricity consumption. The first crucial step in this methodology involved the compilation and verification of a comprehensive dataset representing both the natural energy resources available and the geographical patterns of electricity demand. Primary data sources included official records from the Ministry of Energy of Ukraine, which provided authoritative figures on national and regional energy generation, historical consumption patterns, and planned infrastructure projects. These were complemented by high-resolution data from meteorological stations across Ukraine, allowing for accurate calibration of solar insolation and wind speed measurements over different seasons and terrains. In addition, global datasets from Copernicus and NASA POWER were integrated to fill gaps and provide spatially continuous estimates of solar irradiance, wind potential, and other relevant meteorological variables. The combination of national and international sources enabled the creation of a reliable and high-fidelity dataset suitable for spatially explicit modeling.

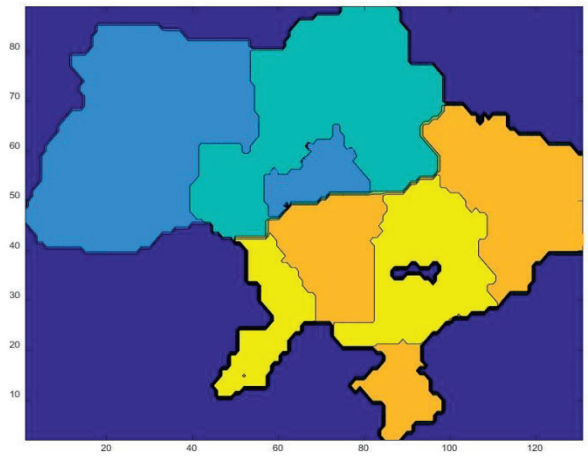
Once the data were gathered, computational tools were employed to process, analyze, and simulate the energy potential across regional grids. MATLAB served as the primary tool for calculating average solar insolation and wind speed across predefined spatial cells, allowing for a detailed mapping of renewable energy availability throughout Ukraine. The modeling in MATLAB considered seasonal variability, topography, and land cover, thereby ensuring that the calculated resource potential reflected real-world constraints. For the optimization of energy transmission and the estimation of losses associated with distance from generation sites to consumption centers, MathCAD was utilized. This software facilitated scenario modeling that included distances between generation regions and major consumption hubs, enabling the simulation of transmission efficiency under varying spatial arrangements of renewable facilities [14-16]



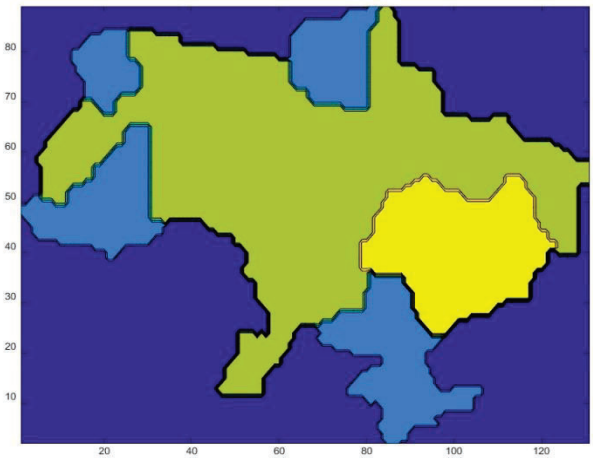
Furthermore, visualization of results required careful post-processing of maps and geospatial data. All figures were exported in high resolution from MATLAB and ArcGIS, with clearly labeled coordinate axes based on the WGS-84 system, annotated legends, and consistent color gradations representing solar potential, wind speeds, and transmission loss percentages. Units of measurement were standardized across all maps, including percentages for energy potential and kilometers for distances, ensuring that the visual outputs were both accurate and interpretable for policy makers, energy planners, and other stakeholders.

Among the visualized spatial data reflecting the potential for electricity production using RES and the configuration of consumption within the national energy system, the materials presented in Fig. 1 became a key source for further analysis.

In Fig 1a and 1b, volatility was not taken into account by us; it was considered by the researchers who created these maps.



a



b

Fig.1 Distribution maps of RES generation (a) and electricity consumption (b) in Ukraine [1–2]

In the process of working with cartographic materials, it was found that most of them do not contain information about the projection system used, which creates difficulties for accurate spatial analysis. In order to ensure correct comparison and spatial unification, all maps were scaled to a single scale based on the maximum lengths of the territory of Ukraine: 1316 km from west to east and 893 km from north to south. To increase the accuracy of modeling, the studied area was discretized in the form of a regular grid of squares with a fixed side length. The resulting images were converted into a 4-bit gradation scale, which made it possible, depending on the original map, to divide the territory into 6 or 4 categories by potential level. This approach allowed creating spatial data arrays that represent the distribution of potential renewable electricity generation and actual energy consumption within Ukraine. These results are visualized in Fig. 2. As can be seen from the presented graphics, regions with the highest potential for renewable energy generation often do not spatially coincide with areas of intensive energy consumption. Such a disparity in the location of generating capacities and consumption centers will inevitably lead to significant losses of electricity in the process of its transportation.

a

b

Fig.2 Distribution maps of renewable energy generation (a) and electricity consumption (b) in Ukraine after recognition and data array creation (values and coordinates correspond to Fig. 1)

Obtaining the distribution of renewable energy generation and electricity consumption in Ukraine allows us to establish possible energy losses during transmission. To determine the share of energy transmitted from one region of Ukraine to another $WT_{j,i}^{k,n}$, the following dependence is proposed

$$WT_{j,i}^{k,n} = W_{j,i}^{R} \frac{W_{k,n}^{C}}{\sum P^{c}} \quad (1)$$

where $W_{j,i}^{R}$ - renewable energy generation potential of the region with coordinates j,i; $W_{k,n}^{C}$ - consumption capacity of the region with coordinates k,n; $\sum P^{c}$ - total capacity of the country's power system.

The above dependence is based on the assumption of a direct proportional dependence of the share of consumption of the country's regions on the total capacity of the country's power system:

$$\sum_{k=1;n=1}^{k=89;n=131} \frac{W_{k,n}^{C}}{\sum P^{c}} = 1 \quad (2)$$

The scheme for calculating losses during transmission of energy from the generation region j,i to the consumption region k,n is shown in Fig.3

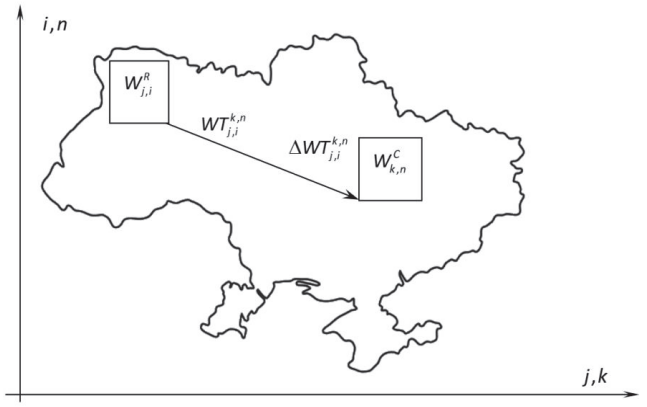


Fig.3 Scheme for calculating the losses of RES potential when transferring energy from the generation area to the consumption area

According to the above methodological recommendations, the loss of active $\Delta W^{(P)}$ or reactive electricity $\Delta W^{(Q)}$ in electrical networks for the calculation period are determined separately for each element of the electrical network (power transmission line, reactor, transformer or autotransformer, etc.) based on the flows of active or reactive electricity at the metering points located on the connected network element in accordance with the generalized formulas:

$$\Delta W^{(P)} = a \cdot I^2 \cdot R \cdot k_f^2 \cdot T^p + P_{y.n} \cdot T_н \quad (3)$$

a - coefficient depending on the type of network (three-phase, single-phase); I - average effective value of the current in the network element; R - active resistance of the network element; k_f^2 - average effective value of the current in the network element; $P_{y.n}$ - conditionally constant losses of active energy in the network element, which depend on the voltage and do not depend on the current strength;

$Q_{y.n}$ - conditionally constant reactive energy losses in a network element, which depend on voltage and do not depend on current strength;

$$\Delta W^{(Q)} = a \cdot I^2 \cdot X \cdot k_f^2 \cdot T^p + Q_{y.n} \cdot T_н \quad (4)$$

X - reactance of the network element;

The use of the dependence is significantly limited by the need to determine the reactive and active resistances of network elements, which depend on a number of structural elements of the power line. At the same time, the use of economic current density $i\ A/mm^2$ allows you to determine power losses under the conditions of choosing the average voltage and the material of the power line conductors

$$\Delta WT = I^2 R = \left(\frac{P}{U}\right)^2 \rho \frac{LUi}{P} = \rho \frac{P}{U} Li \quad (5)$$

where ρ - resistivity; P - power ($WT^{k,n}_{j,i}$);

L - transportation distance.

For the selected stage of development of the algorithm for determining losses, the shortest path for transmitting electrical energy is proposed.

$$L = \Delta l \sqrt{(i-n)^2 + (j-k)^2} \quad (6)$$

Δl - map breakdown step.

The algorithm for determining losses will take into account the density and direction of Ukraine's power supply networks by recognizing power line maps. The results of power losses for individual regions are shown in Fig. 3

Further development of the loss determination algorithm will take into account the density and direction of Ukraine's power supply networks by recognizing power line maps. The results of power losses for individual regions are shown in Fig. 4

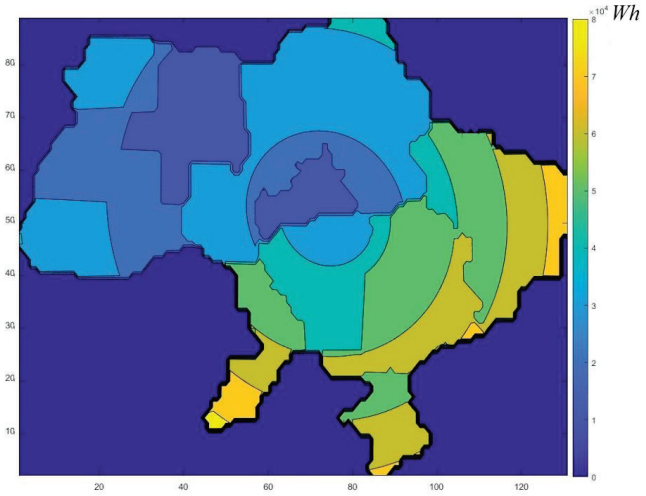

Fig.4 Maps of the distribution of losses predicted during the transmission of renewable electricity, taking into account the remoteness of consumers

As can be seen from the constructed map, the highest losses occur in Kherson, Donetsk, and Luhansk regions, where the losses amount to $7-8 \times 10^{10} Wh$. The lowest costs will be in the central part of Ukraine and in the Zaporizhia region $1-3 \times 10^{10} Wh$.

Analysis of the distribution map of absolute losses of electricity during transmission from renewable sources, taking into account the remoteness of consumers, shows that the location of generators and their remoteness significantly affect the level of losses. The lowest total losses are characteristic of the central regions of Ukraine, while the highest are expected in the eastern and southern regions. The most promising for the development of renewable energy generation are areas with an average level of losses, close to large centers of consumption, in particular the Dnipropetrovsk region and the northern part of the Odessa region [17–18].

To assess the optimal locations for RES, a mathematical model was created in the MATHCAD program, which takes into account the natural potential, power and distance to consumers. The model allowed us to assess the potential of various energy sources and their combinations to select the most effective options for regional development.

Optimization calculations in the MATLAB environment helped to determine the most profitable locations for power plants, taking into account economic aspects, such as infrastructure costs and consumer accessibility [19-24].

IV. CONCLUSION

The analysis of the spatial distribution of transmission losses reveals a strong dependence on the geographic position of Ukrainian regions relative to major electricity consumption centers. The lowest losses are observed in the central regions, including Kyiv and the surrounding areas, where they remain

around 5% due to high consumer density and the compact structure of the grid. A similar situation is found in Zaporizhzhia, where transmission losses are approximately 5–7%. This region also demonstrates exceptionally high solar potential, exceeding 80%, making it one of the most promising areas for further development of renewable generation. Southern regions, particularly Kherson and Mykolaiv, also benefit from high solar radiation levels (over 80%), but their distance from large industrial load centers leads to higher transmission losses. Modeling shows that these losses could be reduced by about 12% if generation facilities were located closer to demand hubs. Western regions occupy an intermediate position: here solar potential is moderate, and transmission losses are higher than in the central areas, though significantly lower than in the eastern regions. The most challenging situation is found in the eastern and northeastern regions, such as Donetsk and Luhansk, where transmission losses exceed 20% due to long distances and grid limitations. At the same time, northern and coastal regions display favorable wind potential, which opens opportunities for combining solar and wind generation strategies

.Overall, the findings highlight that the most effective way to optimize the Ukrainian energy system is to establish decentralized clusters of renewable generation in close proximity to major consumption centers. This approach can reduce transmission losses by 10–15%, improve system reliability, lower infrastructure costs, and simultaneously support environmental sustainability and regional development.

***Abstract*— This study analyzes the susceptibility of IoT microcontrollers to reverse engineering, defined as unauthorized data access for replication, and proposes countermeasures. STM32F0 demonstrates superior resistance due to dense integration, rapid protection activation, and robust encryption, effectively countering attacks like Cold Boot Stepping, Glitch, Electromagnetic Analysis, and invasive methods. GD32 offers moderate security but is vulnerable to faster attacks. CH32 and MM32F0 show the least resilience due to weak protection. Architectural analysis highlights STM32F0's secure interfaces, while GD32's multi-chip design and CH32/MM32F0's simpler cores increase risks. Security metrics confirm STM32F0's lead, with GD32, CH32, and MM32F0 needing enhancements. Recommendations include hardware shielding, signal filters, and dynamic encryption, implementable in 2–14 days at $0.1–1.0 per device. STM32F0 suits high-security IoT, GD32 mid-level needs, and CH32/MM32F0 low-risk applications. Comprehensive hardware and software modifications are critical to mitigate reverse engineering threats across all microcontrollers.**

Keywords— IoT Security, microcontrollers, hardware attacks, protection mechanisms, tncryption.

I. Introduction

The Internet of Things (IoT) has radically changed the approach to device development, providing connectivity in areas such as smart homes, industrial systems, medical devices, and transportation logistics. These devices rely on microcontrollers as the basis of their functionality, providing data processing, peripheral control, and communication with external systems. The STM32 microcontroller series has gained popularity due to its high performance, reliability, and a developed ecosystem that includes development tools, libraries, and technical support [3, 4]. In particular, the STM32F0 family, built on the ARM Cortex-M0 core, is widely used in commercial IoT products due to its optimal price-performance ratio.

However, the growing demand for IoT devices and competition in the market are forcing manufacturers to look for ways to reduce costs. One solution is to switch from the original STM32 to cheaper analogues, such as the GD32, CH32 from WCH and MM32. Consumers expect affordable devices without losing functionality, which forces manufacturers to find compromises between cost and quality. The transition of manufacturers to cheap analogues of microcontrollers carries significant security risks for IoT devices that process confidential data, such as personal user information or industrial parameters. Analogs of STM32, although compatible in terms of pins and software, may have weaker protection mechanisms, which increases their vulnerability to hardware attacks. The multi-chip architecture of the GD32 makes it easier to access flash memory compared to the single-chip design of the STM32, creating additional risks [7, 8, 11]. Reengineering poses a serious threat, causing financial losses to developers [2]. This study focuses on the STM32F0 family, a cost-effective solution for entry-level IoT products. The resistance of these microcontrollers and their counterparts (GD32, CH32, MM32) to four types of hardware attacks is analyzed: Cold Boot Stepping (CBS), Glitch attacks, Electromagnetic Analysis (EMA), and Invasive attacks such as chip decapsulation. CBS exploits the peculiarities of SRAM operation during cold boot to leak data, Glitch attacks manipulate voltage or frequency to bypass protection, EMA analyzes electromagnetic emissions to obtain confidential information, and Invasive attacks involve physical access to the chip [5, 6]. The purpose of the study is to assess the impact of microcontroller choice on the security of IoT devices and to offer recommendations for developers on how to balance cost savings and protection..

II. Main Research

The architecture of a microcontroller is a key factor determining its performance, power consumption, and resistance to hardware attacks aimed at reengineering IoT devices. This study compares microcontrollers:

- STM32F0 by STMicroelectronics;
- GD32 by GigaDevice;
- CH32 by WCH;

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

– MM32 by MindMotion, which are popular in budget IoT applications. These microcontrollers share common features, such as 32-bit architecture and support for peripheral interfaces, but differ significantly in design, security mechanisms, and vulnerability to attacks. The comparison focuses on the single-chip architecture of the STM32F0, the multi-chip structure of the GD32, and the simplified designs of the CH32 and MM32, which affect their security [1, 3, 7, 8,11]. The STM32F0 microcontroller is built on the ARM Cortex-M0 core, which provides a balance between performance and low power consumption. Its single-chip architecture integrates the processor, flash memory, SRAM, and peripheral modules into a single chip, which reduces the physical access points for attacks. The STM32F0 has a flash memory capacity of up to 64 KB, for example, in the STM32F051R8T6 model, and a SRAM capacity of up to 8 KB, which is sufficient for typical IoT tasks such as sensor data processing [3]. Memory protection is implemented through the Readout Protection (RDP) mechanism, which at the RDP2 level blocks access to the flash memory and the debug interface, making reengineering difficult [4]. The single-chip design increases resistance to attacks such as decapsulation, since access to internal components requires high-precision equipment [7].

Unlike the STM32F0, the GD32, specifically the GD32F103, uses a multi-chip architecture where the processor logic and flash memory are placed on separate chips connected by wires via the QSPI protocol [1]. This design reduces manufacturing costs, but creates vulnerabilities, as the connecting wires are potential points for data interception. The GD32 is also based on the ARM Cortex-M3 core, which provides higher performance (up to 108 MHz) compared to the Cortex-M0 in the STM32F0 (up to 48 MHz). The GD32F103 has a flash memory of up to 128 KB and a SRAM of 20 KB, making it attractive for more complex IoT applications [1]. However, the Security Protection mechanism, similar to RDP1, is less robust, allowing access to the SRAM via the debugger, which facilitates reengineering [8].

The CH32 microcontroller, specifically the CH32V103, uses the RISC-V core (QingKe V3), which is an alternative to the ARM architecture. Its architecture is similar to the STM32F0 in terms of single-chip design, but simplified to reduce cost. The CH32 offers up to 64 KB of flash and 20 KB of SRAM, with a maximum frequency of 80 MHz [7]. The lack of hardware encryption and limited protection similar to RDP1 make the CH32 vulnerable to attacks aimed at leaking data for reengineering. MindMotion's MM32F103, built on the ARM Cortex-M0 core, has the simplest architecture among the microcontrollers compared, with up to 64 KB of flash and 8 KB of SRAM, and a frequency of up to 72 MHz [8]. Its protection is limited to basic mechanisms that do not include an RDP2 counterpart, and the weak security coverage facilitates invasive attacks. A comparison of the microcontroller specifications is given in Table 1. which summarizes the key parameters that affect performance and security, including core type, frequency, memory size, architecture, and security level.

The architectural differences of microcontrollers have a direct impact on their resistance to hardware attacks. The single-chip architecture of the STM32F0 and CH32 reduces the number of access points for attacks such as signal interception, but the CH32 loses out due to weaker protection [7]. The multi-chip structure of the GD32 simplifies attacks, in particular through access to QSPI lines that transmit unencrypted data [8]. The MM32, despite its single-chip design, is the most vulnerable due to the lack of robust protection mechanisms and weak chip coverage. These features indicate trade-offs between cost and security: the STM32F0 is the most expensive but the most secure, while the GD32, CH32 and MM32 offer savings at the expense of increased reengineering risk.

TABLE I. TECHNICAL CHARACTERISTICS OF MICROCONTROLLERS

Microcontroller	Core	Frequency (MHz)	Flash memory (KB)	SRAM (KB)	Architecture	Protection
STM32F0	ARM Cortex-M0	48	64	8	Single crystal	RDP1, RDP2
GD32	ARM Cortex-M3	108	128	20	Multi-chip	Security Protection
CH32	RISC-V QingKe V3	80	64	20	Single crystal	Basic (RDP1)
MM32	ARM Cortex-M0	72	64	8	Single crystal	Basic

The comparison of architectures highlights that the choice of microcontroller for IoT devices should be based not only on performance but also on security requirements. The STM32F0 is optimal for applications with high security standards, while the GD32 can be a compromise solution with additional security measures such as isolation of connections. The CH32 and MM32 are suitable for non-critical applications where the risk of reengineering is low [10]. Further analysis in the following sections details the vulnerabilities of each microcontroller to specific attacks.

Microcontroller security mechanisms are the foundation of IoT device security, preventing unauthorized access to firmware and sensitive data, which is critical for protection against reengineering. The STM32F0 microcontroller uses a two-level Readout Protection (RDP) mechanism. RDP1 restricts access to flash memory and SRAM via the debugger using 128-bit encryption of the configuration registers and 8 protected registers. RDP2 completely blocks the debug interfaces (JTAG/SWD), preventing memory reads, and is activated in less than 1 ms after initialization [3]. Testing has shown that RDP2 is resistant to most attacks, except those using side channels [4]. This protection requires careful use, as RDP2 is irreversible and blocks firmware updates.

The GD32 implements a Security Protection mechanism that restricts memory access through 64-bit encryption and 4 protected registers. However, it does not completely block JTAG/SWD, and the activation time is 10 ms, which creates a vulnerability window during initialization [1]. Testing on the GD32F103 has shown that Security Protection does not protect against manipulation of QSPI signals, which facilitates data leakage [8]. This mechanism is a compromise between cost and security, but is less effective in high-security applications.

The CH32 offers basic security, which uses a 32-bit key to restrict memory access via the debugger and only 2 protected registers. There is no encryption, and the protection activation time is 15 ms, making it vulnerable to attacks in the early stages of operation [7]. The MM32 has even weaker protection, without encryption, with a single configuration register and an activation delay of more than 20 ms. Tests have shown that the MM32F103 does not withstand even simple manipulations with the debugger, making it unsuitable for protection against reengineering [8]. Table 2 lists the technical parameters of the protection mechanisms, including numerical indicators reflecting the security level of each microcontroller.

It should be noted that the success rate of attacks is considered as the percentage of successful attempts to bypass protection in tests (CBS, Glitch, EMA) [3, 7, 8,11]. Based on the data presented in Table 1, it can be concluded that the STM32F0, due to its 128-bit encryption, 8 protected registers and fast activation, has the lowest success rate of attacks (10%) [3].

TABLE II. TECHNICAL PARAMETERS OF MICROCONTROLLER PROTECTION MECHANISMS

Microcontroller	Protection levels (number)	Encryption (bits)	Protected registers (number)	Activation time (ms)	Attack success rate (%)
STM32F0	2	128	8	<1	10
GD32	1	64	4	10	60
CH32	1	32	2	15	80
MM32	1	0	1	>20	95

It should be noted that the success rate of attacks is considered as the percentage of successful attempts to bypass protection in tests (CBS, Glitch, EMA) [3, 7, 8]. Based on the data presented in Table 1, it can be concluded that the STM32F0, due to its 128-bit encryption, 8 protected registers and fast activation, has the lowest success rate of attacks (10%) [3]. The GD32, with 64-bit encryption and slower activation, demonstrates average vulnerability (60%) [8]. The CH32 and MM32, with minimal security parameters, have high success rates of attacks (80–95%), which limits their use in critical IoT applications [7].

However, it should be noted that the most significant risks to the security of IoT devices are created by hardware attacks. The paper considers four attack methods [3, 5–9]:

1. Cold Boot Stepping (CBS) uses the residual data in SRAM after power is removed by manipulating the reset signal through a debugger to read keys or firmware. The data retention time is described by the following formula:

$$T_{\text{read}} = T_{reset} + \Delta T_{step} \quad (1)$$

where T_{read} – total time available to read data from SRAM (in milliseconds).

T_{reset} – reset signal delay that keeps the microcontroller in reset state (in milliseconds).

ΔT_{step} – the duration of the step during which the reset signal is briefly removed to read the memory (in microseconds).

To fine-tune the CBS attack (timing) to read the SRAM (microcontroller clock) at the time of initialization, it is necessary to determine the reset signal delay using formula 2.

$$T_{delay} = \frac{1}{f_{clk}} \times k \times V_{dd} \quad (2)$$

where, T_{delay} – reset signal delay (in microseconds).

f_{clk} – microcontroller clock frequency (in MHz).

k – proportionality coefficient, which depends on the hardware implementation (dimensionless quantity).

V_{dd} – microcontroller supply voltage (in volts)

Tests on the STM32F051R8T6 (100 kHz step rate) showed data access in 2–5 ms with weak protection, but blocking in <1 ms with strong protection [5]. The GD32F103 retains data for up to 10 ms due to slow SRAM clearing, which makes it easier to attack with an ANSI32 debugger [8]. The CH32 and MM32 allow reads in 5–15 ms due to slow initialization speed [7].

2. Glitch attacks disrupt the operation of a microcontroller by changing the voltage or clock signal, bypassing security checks. The amplitude of a glitch is described by formula 3 (Aglitch), which takes into account the voltage change and the decay time.

$$A_{glitch} = V_{nom} - \frac{\Delta V}{\tau_{fall}} \quad (3)$$

where, A_{glitch} – glitch amplitude (in volts).

V_{nom} – Rated supply voltage of the microcontroller (in volts).

ΔV – Voltage change during glitch (in volts).

τf_{all} – Voltage fall time (in nanoseconds).

In glitch attacks conducted on STM32F0 using ChipWhisperer-Husky, (dropping to 1.8 V, ΔV=1.5 V, 500 ns) the weak protection was bypassed, but the stronger one required more precise tuning [6]. GD32F103 was attacked at ΔV=1.3 V due to unprotected lines [8]. CH32 and MM32 are vulnerable at ΔV=1.0 V due to lack of stabilization [7]. Countermeasures: voltage stabilizers, randomization of operations [10].

3. Electromagnetic Emissions Analysis (EMA) analyzes electromagnetic signals to obtain data using correlation according to formula 4

$$R = \frac{Cov(\text{E},\text{D})}{\sigma_E \times \sigma_D} \quad (4)$$

where, R – Correlation coefficient (dimensionless value, from -1 to 1).

Cov(E,D): Covariance between measured radiation and data B.

σ_E – Standard deviation of radiation.

σ_D – Standard deviation of data.

4. Invasive attacks and decapsulation involve physical access, including decapsulation, as shown in Fig. 1 and0 Fig. 2 [8].

For the STM32F0, laser decapsulation took 6–12 hours due to dense integration, with memory locking under strong protection [7]. The GD32F103 was chemically attacked in 3–8 hours due to accessible wiring [6]. The CH32 and MM32 were acid-treated in 2–6 hours due to weak

coating [7]. Countermeasures: robust coatings, protected configurations [10].

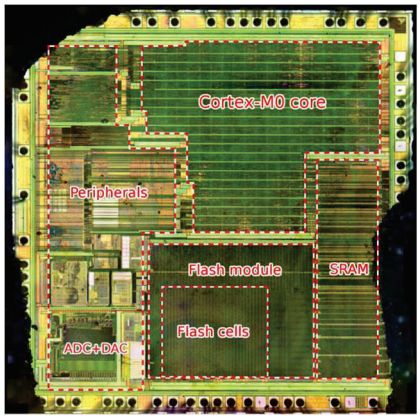

Figure 1: Annotated die of the STM32F051R8T6

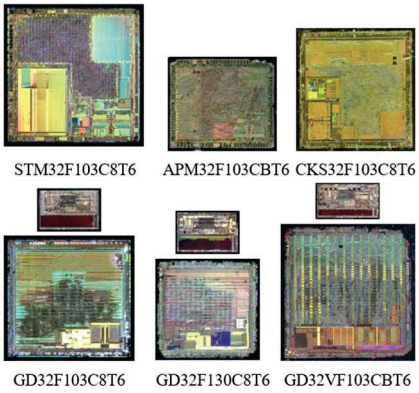

Figure 2 Decapsulated STM32F103 and analogs

In EMA tests on STM32F0 during AES execution, a correlation of R≈0.7 in the range of 100–200 MHz indicated key bit leakage [9]. In GD32F103, the multi-chip architecture increases R due to stronger QSPI line signals, facilitating reengineering. The formula is used for statistical data analysis in CEMA and DEMA methods. Table 3 summarizes the technical parameters of attacks on microcontrollers, including complexity, execution time, hardware, and vulnerability.

TABLE III. TECHNICAL PARAMETERS OF ATTACKS ON MICROCONTROLLERS

Microcontroller	Attack	Difficulty (1–5)	Execution time (hours)	Vulnerability (0–5)
STM32F0	CBS	4	1–2	2
	Glitch	3	2–4	3
	EMA	5	0.5–6	4
	Invasive	4	6–12	4
GD32	CBS	2	0.5–1	4
	Glitch	2	1–3	4
	EMA	3	0.2–4	5
	Invasive	2	3–8	4
CH32	CBS	2	0.5–1	4
	Glitch	2	1–2	4
	EMA	3	0.2–3	5
	Invasive	3	4–10	3
MM32	CBS	1	0.2–0.5	5
	Glitch	1	0.5–1	5
	EMA	2	0.1–2	5
	Invasive	1	2–6	5

The complexity and vulnerability indicators in Table 3 are calculated based on the technical characteristics of attacks and the results of testing conducted under controlled conditions [5–8]. The methodology provides an objective comparison of microcontrollers. Complexity is defined as a combination of three factors: technical requirements (quantity and complexity of equipment, setup time (duration of attack preparation), operator skills (level of expertise). Vulnerability is assessed by two criteria: probability of success (percentage of successful attacks in tests) and data volume (amount of data obtained).

Thus, the initial stage of protecting IoT devices from reengineering is a quantitative assessment of the resistance of microcontrollers to hardware attacks, which is based on an integrative security assessment through formalized indicators and practical implementation measures [3, 5, 7–10].

The analysis of the resistance of microcontrollers to reengineering is based on the security metric (S), which takes into account three technical characteristics: 1) the probability of a successful attack; 2) resource consumption for the attack; 3) attack execution time Table 4. The security metric is calculated by formula 5:

$$S = \frac{1}{P_{attack} \times C_{attack} \times T_{attack}} \quad (5)$$

where: P_{attack} — average probability of success of attacks (CBS, Glitch, EMA, invasive) in percentage (0–1),
C_{attack} — normalized attack complexity (Table 3),
T_{attack} — average attack time in hours.

Additionally, it is proposed to estimate the energy efficiency of protection (Eprot), which takes into account the energy consumption for security activation and the activation time is calculated as:

$$E_{prot} = \frac{W_{prot}}{T_{act}} \quad (6)$$

where W_{prot} — energy consumption (mW),
T_{act} — activation time (ms) [3].
A higher S-parameter indicates a greater resistance of the microcontroller to reengineering [3, 5]

Despite having the highest S index, MM32 is the least stable, as the high value is due to low C_{attack} and T_{attack}, which facilitates attacks. STM32F0 has the lowest S, but this reflects the high complexity and time of attacks, indicating better protection [5]. STM32F0 is also the most efficient in activation speed, which reduces vulnerability to attacks in the early stages.

The data given in Table 5 reflect the technical characteristics of the STM32F0, GD32, CH32 and MM32 microcontrollers in terms of parameters that affect resistance to reengineering. The parameters include: hardware resistance to attacks (the percentage of attacks (CBS, Glitch, EMA, invasive) that did not achieve full access to data in tests [3, 7, 8])software security flexibility (the value of security configuration options, taking into account encryption, randomization [5, 10]), security power consumption and

security implementation costs (the estimated cost of hardware and software modifications per device [7, 8])

TABLE IV. INDICATORS OF MICROCONTROLLER RESISTANCE TO REENGINEERING

Microcontroller	S	P_{attack}	C_{attack}	T_{attack}.	W_{prot} (mW)	T_{act} (ms)	E_{prot} (mW/ms)
STM32F0	0,143	0,35	4	5	5	1	5
GD32	0,185	0,8	2,5	3	8	10	0,8
CH32	0,188	0,85	2,5	2,5	10	15	0,67
MM32F0	0,561	0,95	0,25	1,5	12	20	0,6

According to Table 5, it can be concluded that STM32F0 has the highest hardware resilience, since 90% of attacks (in particular CBS, Glitch) did not achieve full access due to fast protection activation and interface blocking [3].

Software flexibility (5) reflects support for AES-256, randomization and integrity checking [5].

Low power consumption (5 mW) ensures real-time efficiency [3]. Costs ($0.5–1.0) are higher due to the need for shielding and stabilizers [10]. GD32 shows average resilience (60%) due to vulnerability to EMA and CBS, with partial access in 40% of tests [8].

.

TABLE V. TECHNICAL COMPARATIVE ANALYSIS OF MICROCONTROLLERS

Microcontroller	Memory Read Resistance (%)	Protection activation speed (ms)	Attack costs ($/hour)	Hardware complexity of protection (0–5)	Hardware stability (%)	Program flexibility (0–5)	Security costs ($/device)
STM32F0	95	1	100–200	5	90	5	0.5–1.0
GD32	70	10	50–100	3	60	3	0.3–0.7
CH32	50	15	20–50	2	40	2	0.2–0.4
MM32F0	30	20	10–30	1	20	1	0.2–0.4

Software flexibility (3) is limited by 64-bit encryption and basic randomization [6]. Power consumption (8 mW) and costs ($0.3–0.7) are a compromise [8].

CH32 and MM32 have low resistance (40% and 20%) due to 80–95% successful attacks [7]. Software flexibility (2 and 1) is minimal due to weak encryption [7]. High power consumption (10–12 mW) and low cost (0.2–0.4 $) reflect their budget-friendly nature, but limit security [7].

Thus, based on the S and E_{prot} metrics, technical recommendations have been developed to increase the resistance of microcontrollers to reengineering. The recommendations are specific, focused on hardware and software modifications, with clear implementation parameters, namely:

STM32F0: Enable 128-bit encryption of configuration registers with <1 ms latency. Use of 8 security registers to lock JTAG/SWD (CR register = 0xFF) [3]. Implement AES-256 software encryption with 256-bit key to protect firmware with update rate of 1 time/10 minutes (TIM2 register, 600 s) [10]. Electromagnetic shielding (0.5 mm thick, copper foil, resistance <0.1 Ohm) to reduce EMA correlation to R<0.3 [5]. Use of voltage stabilizer (LM317, output 3.3 V ±0.1 V) to protect against glitch attacks with ΔV>1.5 V [6].

GD32: Activation of Security Protection with 64-bit encryption (SPR register = 0xAA). Reduction of activation time to 5 ms by firmware optimization (reduction of initialization cycles by 2 times) [8]. Implementation of software randomization of operations with a delay of 10–50 μs (RNG register, 32-bit generator) to complicate EMA [10]. Isolation of the signal line with 100 Ohm resistors (SMD 0805) to reduce data leakage by 30% [6].

Addition of an external cryptographic module (ATECC608B, I2C, 256-bit key) with consumption <1 mW for SRAM encryption [8].

CH32: Setting a 32-bit security key (CFG register = 0x55). Reducing Tact to 10 ms by removing redundant checks in the firmware (cycle optimization by 50%) [7]. Implementing SHA-256 software encryption with a 32-bit hash for code integrity verification (CRC register, 1 ms/operation) [10]. Adding an epoxy coating (1 mm thick, 10 MPa strength) to increase the time of invasive attacks to 8 hours [7]. Using a voltage stabilizer (AMS1117, 3.3 V ±0.05 V) to block glitch attacks with ΔV>1.0 V [6].

MM32: Activation of basic protection with 1 configuration register (SEC register = 0x11). Reduction of Tact to 15 ms by reducing initialization by 25% [7]. Implementation of AES-128 software encryption with 128-bit key (DMA register, 2 ms/block) for partial SRAM protection [10]. Addition of protective coating (polyurethane, thickness 0.8 mm, strength 8 MPa) to complicate chemical decapsulation by 50% [7]. Use of voltage stabilizer (MCP1700, 3.3 V ±0.1 V) to protect against glitch attacks with ΔV>0.8 V [6].

III. CONCLUSION

The analysis of STM32F0, GD32, CH32, MM32F0 microcontrollers showed that their resistance to reengineering, i.e. unauthorized access to data for reproduction, depends on architectural features, protection mechanisms and vulnerability to hardware attacks. STM32F0 is distinguished by the highest resistance due to dense integration, fast activation of protection and support for complex mechanisms such as multi-level encryption, which significantly complicates attacks such as CBS, Glitch, EMA and invasive methods. GD32 provides an average level of security, but is vulnerable to fast attacks due to slower protection initialization. CH32 and MM32F0 are the least resistant due to weak basic mechanisms and low software flexibility, which facilitates access by attackers.

Practical recommendations for improving security include the implementation of hardware shielding, signal line filters, dynamic encryption and data integrity checks. For STM32F0, these measures are maximally effective, while GD32 requires additional modifications, such as initialization optimization. CH32 and MM32F0 require significant efforts to compensate for vulnerabilities, which limits their use in critical IoT

applications. Implementation of the measures takes from several days to two weeks, with costs of 0.1–1.0 $ / device, depending on the microcontroller.

The STM32F0 is the optimal choice for high-security IoT devices, the GD32 is suitable for medium-security, and the CH32 and MM32F0 are for low-risk, low-cost applications. A comprehensive approach combining hardware and software modifications is necessary for all microcontrollers to minimize reengineering threats and protect intellectual property.

***Abstract*— Satellite fire-detection products like VIIRS effectively identify wildfires but also falsely detect industrial heat sources (steel mills, cement kilns, gas flares) as fires. Such anomalies distort fire patterns, especially in industrial regions. Traditional filtering methods (e.g., removing "static" labeled points) often miss persistent industrial hotspots. We propose a spatial density-based approach using DBSCAN clustering (ε = 138 m, minPts = 20), parameters selected via k-distance analysis. Applied to VIIRS data for Ukraine (2019–2024), the filter captured over 96% of industrial anomalies without affecting real wildfires. This DBSCAN-based method is simple, computationally efficient, and integrates easily into standard GIS workflows, significantly improving wildfire data quality for regions with industrial noise.**

Keywords—VIIRS Active Fire, Thermal Anomaly Noise, DBSCAN Clustering, Spatial filtering, GIS

I. Introduction

Satellite-based fire products, such as VIIRS, detect not only wildfires but also stationary heat emissions from industrial activities (e.g., gas flares, steel mills, cement kilns). Due to VIIRS's geolocation uncertainty (~75 m), these industrial sources create dense "clouds" of repeated hotspot detections around actual facility locations [1]. Such anomalies artificially inflate fire counts and distort spatial analyses, complicating accurate wildfire assessments, especially in industrialized regions.

To manage these industrial false positives, VIIRS data includes a TYPE attribute to classify hotspot sources: vegetation fires (Type 0), volcanoes (Type 1), static land-based sources (Type 2), and offshore sources (Type 3) [2]. Typically, Type 2 hotspots correspond to known industrial emitters, allowing straightforward removal. However, misclassifications frequently occur, with many industrial hotspots incorrectly labeled as vegetation fires (Type 0) or offshore sources (Type 3), leaving residual noise [3]. Consequently, relying only on TYPE attributes is insufficient.

Alternative filtering strategies include manually defined exclusion zones around known industrial sites. For instance, a manually created industrial mask in Indonesia eliminated approximately 13% of fire detections, verified via imagery [4]. Yet, manual methods require significant local expertise, limiting their general applicability.

Spatial clustering approaches, such as hierarchical clustering and DBSCAN, have also been used effectively. For example, hierarchical clustering successfully identified gas flare sites linked to reported emissions in Texas [5], but often depended on predefined facility coordinates. Studies applying DBSCAN clustering generally lacked systematic parameter selection: a previous study in East Asia applied DBSCAN with ε ≈ 0.8 km to separate wildfires from industrial sources [6], while a global Nightfire survey adopted trial-and-error tuning [7]. A spatio-temporal DBSCAN variant (ST-MASK) incorporating temporal dimensions showed promise but still lacked transparent parameter-selection methods [8].

To address these gaps, we propose a reproducible, two-stage DBSCAN filtering workflow. First, a detailed industrial-zone mask was constructed using OpenStreetMap, cadastral records, and high-resolution imagery. Second, DBSCAN was tested systematically across multiple minPts (5, 10, 15, 20), with optimal ε values determined from k-distance curves and validated against the reference mask. The resulting parameter set reliably identifies and removes persistent industrial clusters across different temporal windows and geographic regions, providing an efficient, robust, and readily implementable filtering solution for GIS workflows.

II. Research Methodology

A. Input Data and Preprocessing

The analysis uses VIIRS active-fire detections (375 m resolution) from NASA FIRMS over Ukraine (2019–2024), including attributes such as fire radiative power (FRP, MW) and detection confidence (low, nominal and high) [9–11]. All data were reprojected to EPSG:3035 for accurate distance-based analyses. Only nominal and high-confidence detections were retained for clustering. No preliminary TYPE-based filtering was performed, as industrial anomalies often exhibit inconsistent TYPE classification.

Industrial-zone polygons were obtained from OpenStreetMap (features tagged landuse=industrial, man_made=works) [12,13] and validated using Copernicus Sentinel-2 imagery [14] and cadastral records. To formally account for VIIRS geolocation uncertainty (~75 m), some industrial polygons were buffered by 200 m. This buffered mask provides a reference map of industrial locations, used to calibrate clustering parameters and accurately identify industrial fire anomalies.

B. Density-Driven Clustering with DBSCAN

DBSCAN (Density-Based Spatial Clustering of Applications with Noise) is a clustering algorithm that identifies clusters of arbitrary shape without requiring a predefined number of clusters. It labels isolated points explicitly as noise. DBSCAN relies on two parameters:

- ε (epsilon): defines the radius for local neighborhood searches.
- minPts: sets the minimum number of points required to form a dense cluster.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

The clustering outcome is highly sensitive to the chosen parameters: if ε is too small genuine clusters fragment into noise, whereas a too large ε merges distinct clusters or includes spurious points [15, 16].

Since the choice of DBSCAN parameters significantly impacts clustering quality and is highly task-specific, we propose a systematic calibration method tailored to our application. The details of our parameter selection approach are described in the following section.

III. Results and Discussion

A. The Attribute-Based Filtering TYPE Flags

Many studies have proposed filtering industrial thermal anomalies by using the VIIRS TYPE attribute, which indicates the algorithm's inferred source of the thermal anomaly. The TYPE classification scheme labels detections as presumed vegetation fires (TYPE = 0), active volcanoes (TYPE = 1), static land-based sources (TYPE = 2), or offshore sources (TYPE = 3).

To assess the effectiveness of the TYPE filter, we examined the overlap between VIIRS detections (2019–2024) and our validated industrial-zone mask. After excluding all non-TYPE = 0 points, 22 378 detections—about 5% of the 414 003 total VIIRS detections—still fall within industrial polygons. This represents approximately 31% of the original 71 565 industrial detections, confirming that numerous factory- and kiln-related thermal anomalies are misclassified as vegetation fires (TYPE = 0) rather than being correctly labeled as static sources (TYPE = 2).

Thus, while the TYPE attribute provides a useful first-pass filter for identifying known static sources, it fails to reliably exclude all industrial thermal anomalies.

B. Selecting DBSCAN Parameters for Industrial Thermal Anomaly Filtering

Since simple attribute-based filtering or FRP thresholding of VIIRS thermal anomaly points proved insufficient to eliminate the dense jitter clouds over industrial sites we applied a density-based spatial clustering filter using the DBSCAN algorithm.

To capture the full density structure of industrial anomalies, we built k-distance plots from all high-confidence detections within the buffered industrial-zone mask. These knees provide a data-driven basis for selecting ε intervals prior to final tuning [16].

Fig. 1 illustrates the k-distance curves derived from industrial fire points for several values of minPts (5, 10, 15, and 20). As expected, the estimated ε decreases with lower minPts, reflecting the fact that smaller clusters require less spatial cohesion to meet the density threshold. Conversely, higher minPts values capture only more persistent and spatially concentrated point groupings, leading to larger ε values at the inflection point. Rather than fixing minPts in advance, we adopted a two-step approach: first, for each minPts setting we determined an appropriate ε interval based on the location of the inflection point in the corresponding curve. We then identified the optimal ε that minimized the absolute count error with respect to the known number of industrial fire points (22 378), where this value represents the total number of points with TYPE = 0 falling within the industrial zone mask.

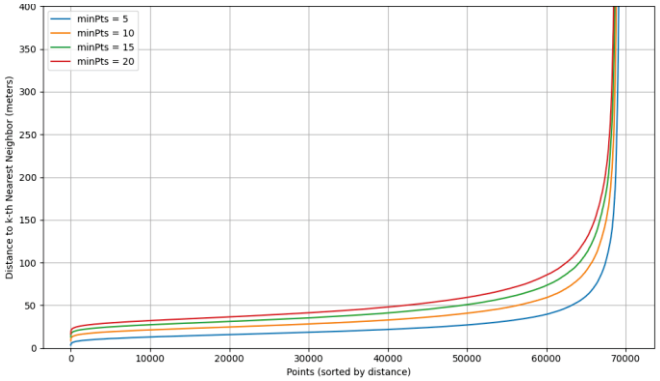

Fig. 1. k-distance plots for industrial fire points (*minPts* = 5–20)

We then performed a scripted grid-search: for each minPts (5, 10, 15, 20), we varied ε within its knee-derived interval and computed the absolute count error as (1).

$$E_{count}(\varepsilon) = \left| N_{clustered}(\varepsilon) - N_{ref} \right|, \tag{1}$$

where $N_{clustered}(\varepsilon)$ is the number of points DBSCAN assigns to any cluster and N_{ref}= 22 378 is the reference count of points in the buffered mask. The optimal radius ε^* (2).

$$\varepsilon^* = \arg\min_{\varepsilon} E_{count}(\varepsilon) \tag{2}$$

is therefore the value that makes the clustered count match N_{ref} most closely. This approach yields parameters that balance capturing the core jitter clouds and covering the full industrial footprint without over-smoothing.

In the second stage of the analysis, we generated DBSCAN clusters using the selected (ε, *minPts*) combinations and spatially evaluated the resulting cluster layers against a polygonal mask of industrial zones. After dissolving all cluster hulls into a single mask and performing unique-point counting, we measured both the count-based error and spatial overlap metrics for each minPts. This comparison allowed us to assess which minPts value resulted in clusters most spatially consistent with known industrial areas. This dual optimization ensured that the final parameters captured not only the correct number of industrial fire points but also their expected geographic distribution. Although VIIRS pixels nominally span 375 m on a side, the k-distance analysis consistently reveals optimal ε values of 70–140 m (see Table I) – well below that spatial granularity. This is not a contradiction but a direct consequence of VIIRS Level-1B geolocation uncertainty (1-σ ≅ 75 m) rather than the sensor's pixel footprint. Repeated detections of the same fixed heat source scatter around the true location by tens of metres, producing a dense "jitter cloud" whose internal point spacing is governed by sub-pixel positioning errors. Thus, choosing ε at roughly the 5th-neighbor knee (≈ 73 m) and 20th-neighbor knee (≈ 138 m) effectively isolates these jitter swarms without conflating distinct facilities or wildfire events.

TABLE I. DBSCAN PARAMETER TUNING RESULTS FOR VARYING MINPTS VALUES

Parameters	*minPts*			
	5	**10**	**15**	**20**
ε range tested (m)	40–100	60–120	80–140	90–160
optimal ε (m)	73	100	124	138
$N_{clustered}(\varepsilon)$	22373	22369	22398	22374
Abs. error	5	9	20	4
% in industrial zones (precision)	94.25%	94.33%	94.37%	94.40%
number of clusters	283	94	71	66
min. cluster area, km^2	3.4e-5	7.71e-3	0.011	0.035
max. cluster area, km^2	5.650	9.614	9.784	9.847

Based on the multi-criteria results summarized in Table II, we selected minPts = 20 for our final DBSCAN configuration. With this setting (and an optimal ε = 138 m), the filter achieves the highest spatial precision, as 94.40 % of clustered points fall within the industrial-zone mask. Here, "% in industrial zones" is computed as the ratio of unique clustered points whose centroids intersect the polygonal mask of known industrial areas to the total number of clustered points, thereby quantifying the filter's specificity. Moreover, increasing minPts to 20 dramatically reduces over-fragmentation: only 66 clusters are detected (compared to 283 when minPts = 5), and the minimum cluster area (0.0347 km²) aligns well with the typical scale of actual industrial facilities. In contrast, lower minPts values produce many small, dispersed clusters – often outside known industrial zones – thereby compromising precision.

To evaluate the performance of the DBSCAN-based filtering approach, we compared the resulting cluster coverage against a labeled subset of industrial thermal anomaly points (TYPE = 2). A total of 40 913 such points were present in the unfiltered dataset. Spatial intersection analysis revealed that 40 471 of them (98.92%) were captured within the polygons of DBSCAN clusters generated using the parameters ε = 138 m and minPts = 20 (Table II). Only 1.08% points remained outside cluster boundaries. This near-complete overlap confirms that the density-based filtering method accurately identifies the spatial signature of persistent industrial hotspots.

To illustrate the spatial benefits of density-based filtering, we examined VIIRS detections (2019–2024) at ArcelorMittal Kryvyi Rih – one of Ukraine's largest metallurgical complexes (Fig. 2).

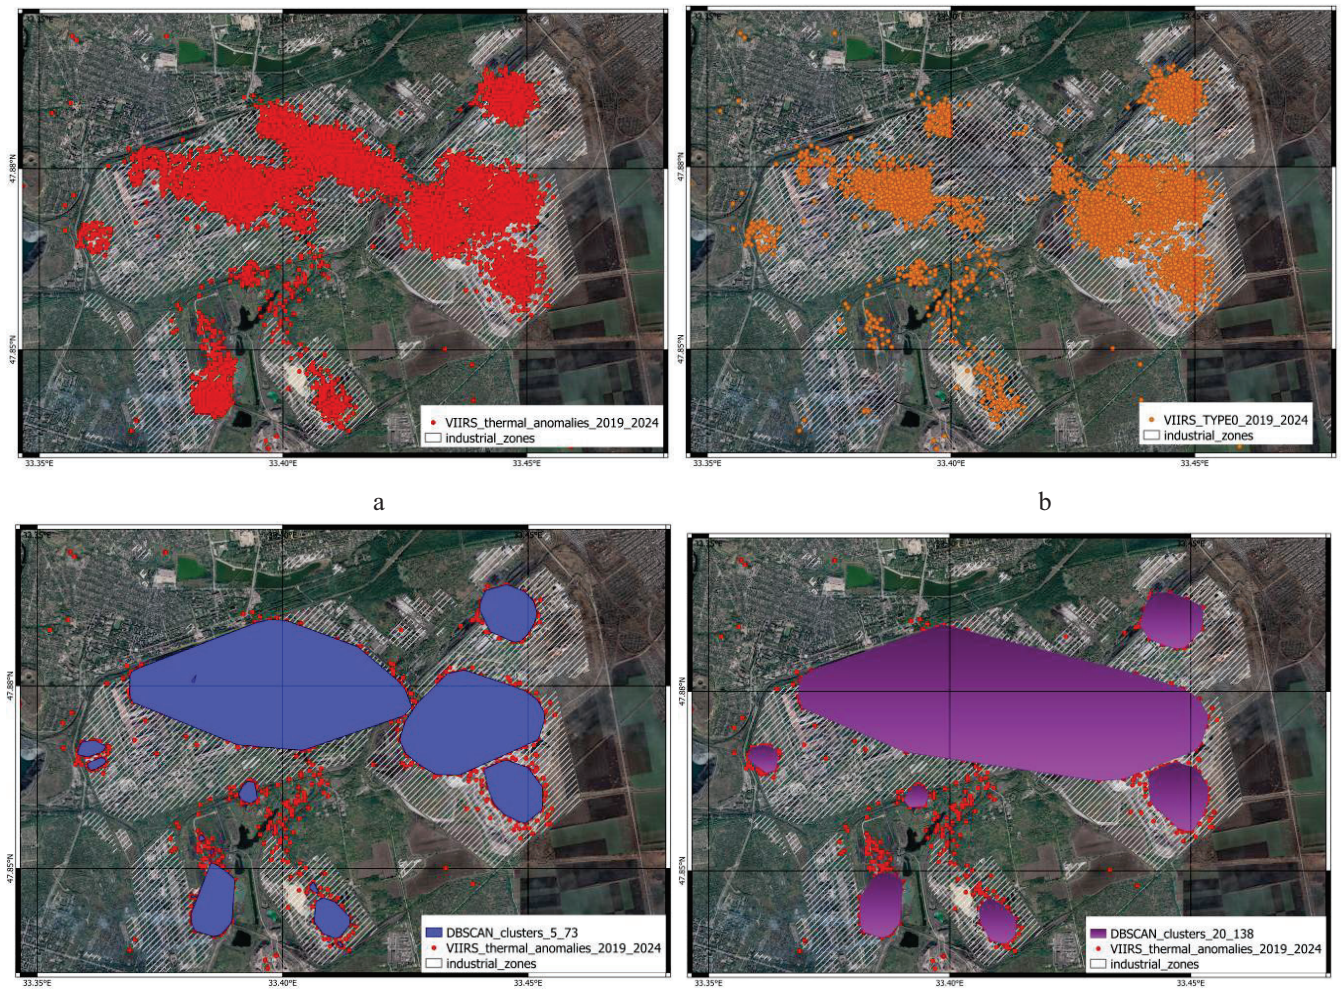

Fig. 2. Thermal anomaly clustering at PJSC ArcelorMittal Kryvyi Rih: a) All VIIRS detections (2019–2024); b) Filtered anomalies (TYPE = 0); c) DBSCAN clusters (minPts = 5, ε = 73 m); d) DBSCAN clusters (minPts = 20, ε = 138 m)

TABLE II. DISTRIBUTION OF POINTS IN INDUSTRIAL MASK AND CLUSTER CAPTURE BY TYPE (2019-2024)

TYPE	Total points	Points in industrial zones	% of Total	Points in clusters	% of Total
0	362 322	22 378	6.16%	22 374	6.18%
2	40 913	38453	93.99%	40471	98.92%
3	10 768	9279	86.17%	9563	88.81%
Total	414 033	70 110	16.93%	72408	17.49%

After excluding all TYPE=2 points, numerous "hotspots" still lay within the plant boundary, underscoring the insufficiency of attribute-only filters (Fig. 2b).

Although our 5-year analysis in Ukraine identified minPts = 20 as optimal for capturing truly persistent clusters over multi-year intervals (Fig. 2d), this choice is by no means universal. Rather than prescribing specific minPts values, we recommend a general guiding principle: minPts should scale with the number of VIIRS overpasses in the chosen time window, so that clusters reflect genuinely stationary sources rather than transient events. For longer, multi-year intervals – when a fixed industrial facility may be imaged dozens of times – higher minPts values are appropriate (e.g., minPts ≈ 20); for shorter, monthly intervals – when only a handful of detections occur – lower values (e.g., minPts ≈ 5) suffice (Fig. 2c). In practice, one can calculate the total number of overpasses (or detections) expected during the analysis period and set minPts to a fraction (for example, 20–30 %) of that count to capture only those anomalies that recur consistently throughout the window. This data-driven scaling ensures that DBSCAN isolates truly stationary industrial hotspots at any temporal granularity, from multi-year to monthly studies.

IV. CONCLUSIONS

In this work, we have shown that conventional attribute- or intensity-based filters are unable to fully remove persistent industrial thermal anomalies – and the attendant sub-pixel "jitter clouds" caused by VIIRS Level-1B geolocation errors – from satellite active-fire datasets. By introducing a density-based clustering step (DBSCAN) with parameters selected via k-distance analysis and count-error minimization against an industrial-zone mask, we achieve robust removal of industrial noise while preserving genuine wildfire detections.

Crucially, we find that all tested (ε, MinPts) combinations yield acceptable precision (> 94 %) over multi-year intervals, and that MinPts should scale with the number of VIIRS overpasses in the chosen time window. Higher MinPts values suit multi-year analyses, while shorter intervals (annual, monthly) call for proportionally lower MinPts to isolate truly persistent sources. This data-driven scaling ensures the method's applicability at any temporal granularity.

Looking forward, integrating spatio-temporal clustering (e.g., ST-DBSCAN) could further discriminate transient wildfire bursts from stationary industrial sources. Finally, embedding this lightweight, two-parameter filter into operational fire-monitoring workflows promises cleaner, more accurate wildfire trend analyses in heavily industrialized regions.

***Abstract*—The paper considers the issues of determining the force and stiffness characteristics of a controlled axial magnetic support using analytical and numerical mathematical modelling. This support is a disk on a movable rod or shaft (depending on the design purpose), which is located between two symmetrical cores of the armored type. Due to the application in the system controlling the axial position of the disk, almost any law of control of force electromagnets, this electromechanical support provides the required vibration-damping and vibration-isolating characteristics. In the case of a horizontal position of the shaft, the considered support is an axial thrust active magnetic bearing, which for research is practically implemented in an operating laboratory rig of a full magnetic suspension of a rotating model rotor in two radial passive magnetic bearings made of rare-earth annular permanent magnets. In the case of a vertical position of the shaft, this magnetic suspension can be considered as a whole as a passive-active vibration-damping and vibration-isolating complex support for either a load located on top, or a body suspended from below. Then the rotor is considered as a non-rotating rod-shaft that holds the vibration-isolated load. In the first and second cases, the accuracy of the dynamic characteristics of this mechatronic system depends on the accuracy of the design calculation of the axial active magnetic support characteristics from the point of view of the possibility of damping the parasitic vibrations of the working body, that is, the suspension object (rotor or load). With the use of analytical and numerical approaches, the possibilities of determining strength and stiffness characteristics depending on the parameters of the axial magnetic support and the control system are investigated. Distinctive features inherent in these two approaches in solving the given problem are shown, with an analysis of their influence on the accuracy of the simulation. The results of analyzes with their verification are given. For the laboratory rig, the possibility of its use as a whole as a vibration-damping and vibration-isolating complex fully magnetic passive-active type support has been confirmed. If necessary, with relatively large dimensions and mass parameters of the object of vibration isolation, a combination of several such complex supports can be used, acting in concert due to the use of cross connections in the control systems of the axial electromagnetic support element, which is the subject of this work.**

Keywords— axial active magnetic support, magnetic bearing, electromagnetic circuit, control system and law, analytical and numerical models, magnetic force and stiffness, laboratory rig

I. Introduction

One of the main issues in the creation and operation of machines, mechanisms, devices, and equipment for various purposes is the reduction or even elimination of possible vibrations of individual structural elements or the structure as a whole [1]. Such mechanical vibrations are caused by various dynamic effects [2], which can be generated by the operating modes of the components (such as, for example, the rotor or shaft of a fan, turbogenerator, turbocompressor with residual imbalance) or caused by external factors (earthquake, the supporting vehicle platform motion on a rough road, the fall of a watercraft in stormy conditions or an aircraft in the turbulence zone, impacts of various nature, etc.). In all these cases, the excitation of mono- or polyharmonic mechanical oscillations (vibrations) with large amplitudes, especially in resonant modes, can lead to the destruction or damage of the main structural elements. Such structural elements are often objects of vibration isolation or vibration damping. The purpose of this process is not to transmit the vibration energy passing through the more durable components of the structure from the source to the most vulnerable working or executive element. This element can be a rotor of a turbomachine with impellers, a measuring device on a moving base or a platform that requires precise guidance of a weapon, a mobile hospital bed, etc.

Currently, new types of vibration dampers and isolators are being created and widely used, including those based on the principle of quasi-zero stiffness, for vibration protection of devices, equipment, cargo, and people from dynamic effects in extreme conditions. Therefore, this topic is relevant in various areas throughout the entire period of development of technical devices, including at the present time.

II. Literature Review

To achieve the described goal, two main approaches are used – vibration damping and vibration isolation. Vibration damping or dynamic damping is the introduction of additional mass into the vibrating system or an increase in the stiffness of the system. Dynamic vibration dampers of various types are used for this purpose: spring, impact, pendulum, eccentric, hydraulic, and others [3]. These elements can be of passive or active types [4, 5]. The disadvantage of a dynamic damper is that it operates only at a certain frequency, which corresponds to its resonant mode of vibrations. This problem can be solved by electromagnetic

dampers due to the implementation of a certain control law [6-8], which allows changing the mechanical stiffness and/or damping properties (for example, by changing the active resistance in the circuit to convert a larger amount of kinetic energy into thermal energy). Vibration isolation is an introduction of an additional elastic connection into the vibrating system with the aim of weakening the transmission of vibrations to the protected object (adjacent element, structure or workplace) from the excitation source. Vibration isolation is carried out by installing a vibration source on vibration isolators [9]. Among them, there are also vibration isolators based on electromagnetic interaction, and they can also be of active or passive types [10]. A separate class of vibration isolators are vibration isolation systems with quasi-zero stiffness (QZS) [11]. Vibration isolators of this type implement the QZS characteristic by combining components with positive stiffness and components with negative stiffness. In this case, the addition of non-linear force characteristics of two components allows creating ranges of zero stiffness on the total force characteristics that correspond to the working position of the object of vibration isolation. This enables effective isolation of low-frequency vibrations, providing sufficient load-bearing capacity and maintaining the system stability. Such systems are now used in ultra-precise production and various precise measurements, in aerospace detection, in regular and non-regular work or delivery of weapons, equipment or people, for example, in extreme conditions with an explosive hazard. Passive vibration isolation systems QZS mainly include mechanical springs [12], pre-bent beams [13], geometrically nonlinear structures [14], electromagnetic and magnetic structures from permanent magnets [15, 16], bio-inspired structures [17], and composite structures [18]. For magnetic elements of negative stiffness, a special arrangement of magnets is used, allowing easily controlling the negative stiffness characteristic. Active and semi-active elements of negative stiffness [19, 20] are basically electromagnetic devices and can better adapt to various conditions based on displacement feedback.

Thus, one of the progressive mechanisms of building vibration damping or vibration isolation systems is the use of uncontrolled and controlled, i.e. passive or active, magnetic or electromagnetic elements to ensure the required damping or force characteristics [21, 22]. Dampers based on such principles include eddy current and coil dampers [23, 24], permanent magnet dampers, active and semi-active electromagnetic dampers (EMD) [25, 26]. At the same time, active EMDs use control systems (CS) to actively adjust the damping force, while semi-active EMDs use, for example, a variable resistor or another method to change damping [27]. The task of the electromagnetic damping system, as well as based on the other principles, is to transform the kinetic energy of mechanical vibrations into another type of energy, for example, into thermal energy.

The principle of operation of the insulator with quasi-zero stiffness is demonstrated in Fig. 1. The element of positive stiffness (PS) is connected to the element of negative stiffness (NS) and within the working range, the offset $[x_1, x_2]$ forms a range of zero stiffness. This range is determined by the static load, for example, the weight of the vibration isolation object. In this case, when the base is dynamically excited, the vibration is not transmitted through such a vibration isolator.

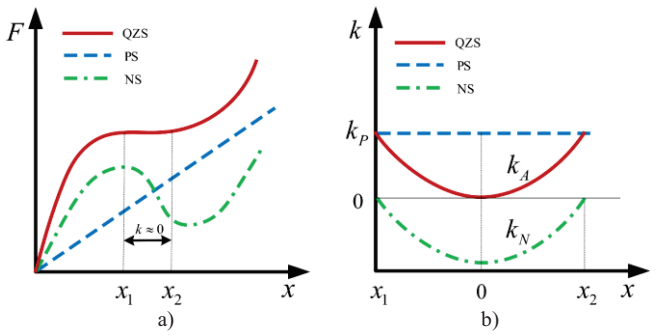

Fig. 1. The QZS vibration isolator operation principle [9]: a) force F vs displacement x dependence; b) stiffness k vs displacement x dependence

Electromagnetic dampers, vibration dampers and vibration isolators, including QZS, are essentially mechatronic systems and are designed based on simulations in various ways. For example, the works [28, 29] describe analytical and numerical approaches for evaluating the characteristics of various electromagnetic dampers and vibration dampers with verification based on experimental data [30]. The same methods are used for mathematical modelling and determination of properties and characteristics of semi-active [31] and active [32, 33] vibration isolators.

In both cases, either when applying the principles of vibration damping, or when applying vibration isolation mechanisms, the question of exact parametric determination of the characteristics created for a specific system of vibration dampers or vibration isolators is always acute. This study is devoted to considering the possibilities of analytical or numerical modelling for the analysis of damping elements based on magnetic or electromagnetic interaction.

III. The Aim and Object of Research

The aim of the research is the analytical and numerical determination of the force and stiffness characteristics of an axially controlled magnetic support with a comparative analysis to identify its pros and cons, as well as assessing the possibilities of using the considered support type as a vibration-damping or vibration-isolating structural element.

The object of research is one of axial controlled electromagnetic support types. This support is practically implemented in the form of a thrust bearing in a laboratory-experimental rig (Fig. 2) of a complete combined magnetic-electromagnetic rotor suspension and is a disk on a shaft, which is located between two symmetrical cores of the armor type [34]. The scheme of the control system of this support as an axial active magnetic bearing (AMB) is shown in Fig. 3 along with the force characteristics of radial annular passive magnetic bearings (PMBs) made of rare earth materials (NdFeB alloy). Complete rotor magnetic suspensions are widely used in various machines like turbocompressors of gas-pumping units [35], and the rig was created to study the possibility of replacing radial active magnetic bearings with passive ones [36], as well as to study the influence of various factors [37, 38] and dynamic excitations [39].

The laboratory-experimental rig has the following parameters of the structural elements: mass of the rotor m=2.496 kg, diametral mass moment of inertia (MOI) J_1=0.0107386 kg·m^2, polar mass MOI J_3=0.0033177 kg·m^2; the distance from the left and right PMBs to the center of gravity of the rotor, respectively l_1=0.107 and l_2=0.177 m, radial PMB clearance δ_r=5.5·10^{-3} m.

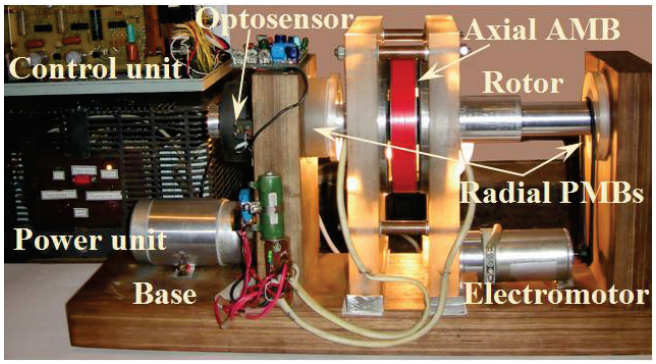

Fig. 2. Laboratory-experimental rig of a model rotor combined magnetic-electromagnetic suspension.

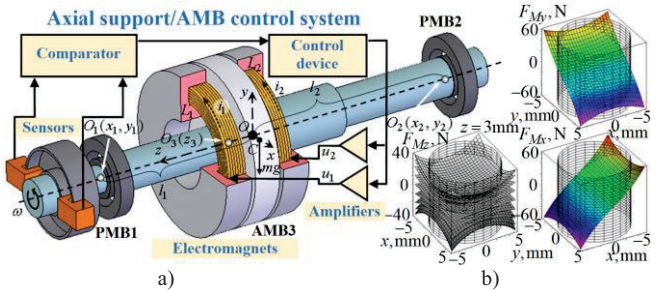

Fig. 3. Complete magnetic-electromagnetic suspension model rotor: a) structural diagram of the control system of a thrust AMB (axial support); b) force characteristics of radial PMBs.

The axial AMB is presented in Fig. 4 and has the following parameters: outer and inner diameters of electromagnets (EMs) 3 and 4 – 0.12 and 0.05 m, lengths of each EM 3 and 4 in the axial direction – 0.021 m, outer and inner diameters of the windings 5 – 0.1 and 0.072 m, the number of winding turns – 300, active resistance of the windings – $r_{c1,2}$=5 Ohm, thickness of the disk 2 on the shaft 1 – 0.02 m, nominal clearance from each side – δ_a=3 mm, basic control voltage U_0=24 V, control frequency 300-400 Hz [34].

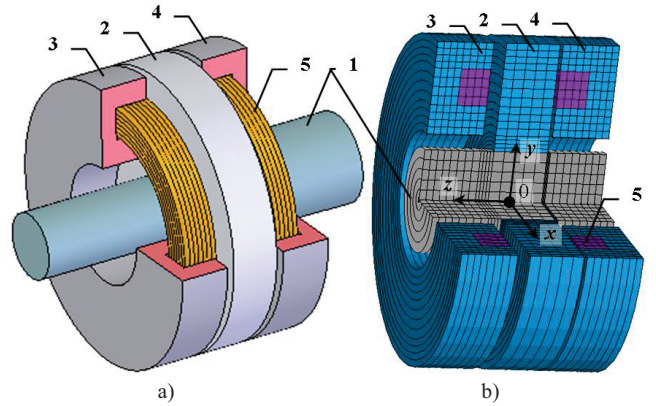

Fig. 4. Models of a thrust AMB (axial support): a) geometric model with a centrally located disk; b) finite element model with an offset disk.

IV. Approaches to Mathematical Determination of Force Characteristics of Axial Controlled Support

Different approaches can be used to calculate the force and stiffness characteristics of an axial electromagnetic support. Analytical and numerical methods are the most practical. Each of them has its advantages and disadvantages. Therefore, the analytical method of AMB electromagnetic circuit analysis [40, 41] is used as an analytical approach, based on the introduction of detailed equivalent schemes for the replacement of magnetic circuits and the application of the method of contour flows. The finite element method is used as a numerical approach [41, 42].

For the correct determination of the dependences of restoring forces on displacement and currents in the windings of EMs in the supports, the control law must be considered. For the laboratory-experimental rig (Fig. 2, Fig. 3), the control obeys the law in the form of quadratic dependences of the average voltage $u_{c1,2}$ on the AMB windings, which provide a given change in the average currents $i_{c1,2}$ in accordance with the adopted control parameter k_i (without taking into account the constant time of the change of currents in the EM windings due to inductance):

$$i_{c1,2}=\frac{(i_{\max}-2i_{\min})z_3^2}{2\delta_a^2}\mp\frac{i_{\max}z_3}{2\delta_a}+i_{\min},\ u_{c1,2}=r_{c1,2}\,i_{c1,2},\quad (1)$$

where $i_{\max}=U_0/r_{c1,2}$, $r_{c1}=r_{c2}$, $i_{\min}=k_i i_{\max}$.

The bias current $i_{\min}$ in (1) cannot be equal to 0, so its value creates a preload and provides the required stiffness in the equilibrium position (at the central position).

A. Analytical determination of magnetic forces

For the analytical description of the system, a detailed equivalent scheme of the substitution of magnetic circuits is used, considering the scattering fluxes through the grooves filled with copper windings. This scheme was synthesized as a result of the analysis of the magnetic field equipotential line distribution (Fig. 5a) and is presented in Fig. 5b, where the designations are introduced: Φ_k – magnetic fluxes in sections of the circuit; Φ_{Ck} – contour fluxes; R_k – magnetic resistance of sections of the circuit, and R_{pk} – of poles, R_{gk} – of air gaps between poles and a rotor, R_{sk} – of sections of a stator yoke between two poles, R_{lk} – of scattering between poles (grooves filled with copper winding), R_{ak}=R_a – of a disk; e_k=$i_{ck}w_k$ – coil magnetomotive forces.

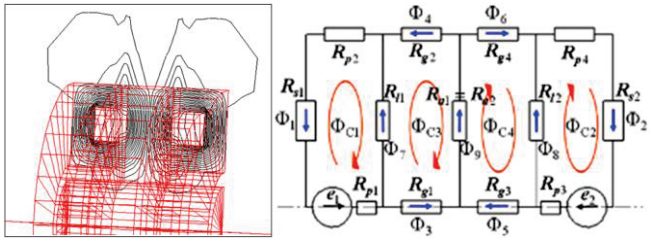

Fig. 5. Equipotential magnetic field lines: at the central position of the disk (left) and the equivalent scheme of the substitution of magnetic circuits taking into account the scattering fluxes (right).

The magnetic energy of the axial AMB (the entire magnetic circuit energy as the circuit sections energies sum):

$$W=\frac{1}{2}\left[\begin{array}{l}(R_{s1}+R_{p1}+R_{p2})\Phi_1^2+(R_{s2}+R_{p3}+R_{p4})\Phi_2^2+R_{g1}\Phi_3^2+\\+R_{g2}\Phi_4^2+R_{g3}\Phi_5^2+R_{g4}\Phi_6^2+R_{l1}\Phi_7^2+R_{l2}\Phi_8^2+R_{a1}\Phi_9^2\end{array}\right].\quad (2)$$

Applying the method of contour fluxes and considering that the magnetic resistance of the air gaps depends on the displacement of the disk relative to the central position give the expression of the electromagnetic force:

$$F_{Mqj}=-\frac{\partial W}{\partial q_j},\ q_j=\{x_1,y_1,x_2,y_2,z_3\}.\quad (3)$$

As a result of the variant analysis using this approach, the force characteristics were obtained. Fig. 6a shows the type of control law (1) corresponding to the previously adopted CS parameters, and Fig. 6b shows the dependences of forces on the disk axial displacement for these parameters. The current values marked with dots correspond to the experimental conditions, and discrepancy between the force characteristic for a plane-parallel gap (thick purple line) and experimental data is less than 3%. Fig. 6b also illustrates the change in the force characteristics for different disk tilts (gray lines of different gradations). Analysis of the results showed that the error in calculating the forces without considering the dependence on disk tilt can exceed 30%.

Changing the parameters of the control law as shown in Fig. 6c, 6d, other force characteristics can be obtained both for a plane-parallel gap and different levels of disk tilt relative to the axis within the geometrically possible states considering the axial gap. A certain ratio of the system parameters can achieve a constant range on the force characteristic, i.e. a quasi-zero stiffness range, as shown in Fig. 6e, 6f within the displacement range of -0.001..0.001 m.

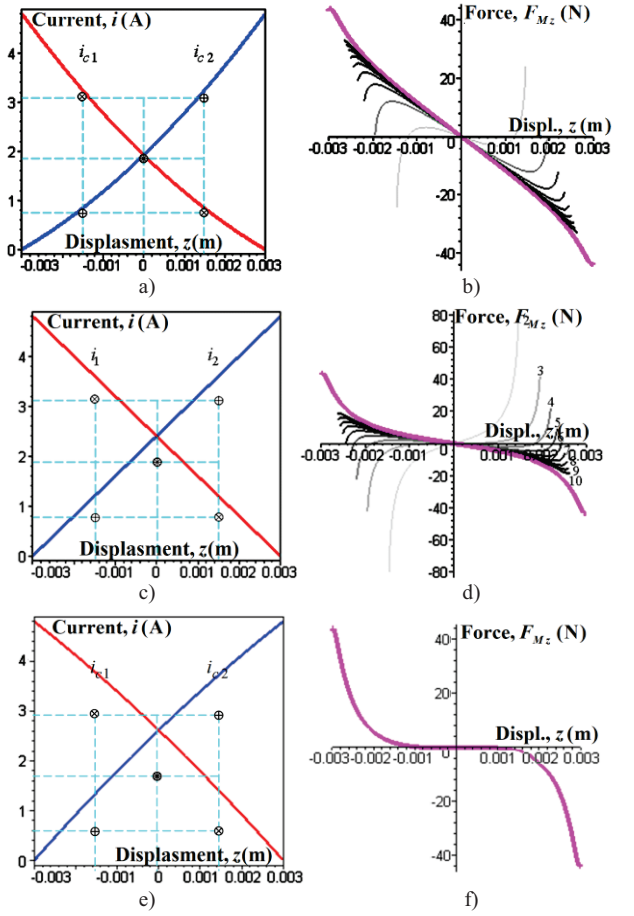

Fig. 6. Force characteristics of the AAMS with different control law parameters k_i: a) change in average currents for k_i=0.4; b) dependence of magnetic force for k_i=0.4; c) change in average currents for k_i=0.5; d) dependence of magnetic force for k_i=0.5; e) change in average currents for k_i=0.545; f) dependence of magnetic force for k_i=0.545.

The analytical approach advantage is the possibility of precise mathematical calculation of the electromagnetic force value depending on the disk coordinates considering disk tilt with low time and system resource costs allowing conducting multivariate studies to select rational or optimal design parameters and control systems. The disadvantages of the approach are a failure to include the design spatiality, as well as consideration only of some main paths of magnetic flux propagation in the equivalent circuit in accordance with the adopted simplifications (Fig. 5b), which can negatively affect the accuracy of determining magnetic forces.

B. Numerical determination of magnetic forces

The strategy for numerical determination of magnetic forces is based on the application of the finite element approach and solution of the magnetostatics problem in a volumetric formulation for a specific position of the disk on the shaft section using a finite element model with a plane-parallel air working gap, like that shown in Fig. 4b [42, 43]. During calculations, elements simulating the air in the gaps and grooves, as well as around all parts, are added to this model. Conditions at infinity are set at the outer boundaries of the air. The load is specified as the current density in the elements simulating the windings of both EMs, considering the direction in each of them. The current density in each winding corresponds to the current value determined by the control law for a specific disk displacement. In this case, the mathematical model is formed relative to the components of the vector magnetic potential [42, 43]. As a result, the spatial distributions of the magnetic induction vectors and magnetic field strength moduli are determined (Fig. 5a). Magnetic forces are calculated using the Maxwell stress tensor or the virtual work principle. The force characteristic is constructed based on the results of analyses for different disk positions within the gap using approximation by a nonlinear polynomial of odd degree based on discrete calculated values. Stiffness is determined as the first derivative of the force in the direction with the opposite sign, i.e. K_M=-$\partial F_M/\partial z$.

Fig. 7a, 7b shows force and stiffness characteristics of the axial active magnetic support (AAMS) with the control law initial parameters (1) corresponding to Fig. 6a. Comparison of the experimental and calculated approximated values gave a relative difference <1%, which is less than when using the analytical approach (Fig. 6b). Fig. 7c, 7d presents the same results, but with different values of the basic control voltage when using pulse-width modulation in the control system [34] showing that changing the basic supply voltage allows achieving the presence of quasi-zero stiffness range.

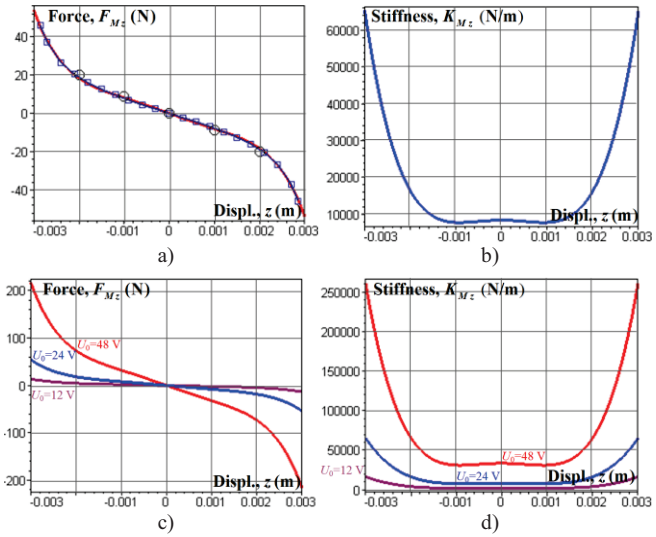

Fig. 7. Dependence of the AAMS characteristics on the disk displacement with the control law parameters (CLPs) (○ – experimental and □ – calculated data): a) magnetic force for intial CLPs; b) stiffness for initial CLPs; c) magnetic force for varios CLPs; d) stiffness for varios CLPs.

The numerical approach advantage is the possibility of considering magnetic flux spatial distribution, which practically coincides with the real one, see in Fig. 5 (left). This allows taking into account all the features (fluxes along the sections of the magnetic circuit of moving and stationary parts, air gaps outside the magnetic circuits, including parasitic and scattering, and others) and increasing the result accuracy. Parametric automation allows for a variant search for the best designs. The approach disadvantages include the complexity of implementing the disk tilt in the calculated finite element model within the topological limitations of a small gap. It is associated with a large error caused by mesh discretization due to the presence of relatively small elements with a degenerate shape. In addition, the numerical method requires a much larger system and time resources.

V. Passive-Active Vibration-Damping and Vibration-Isolating Complex Magnetic Support

The results of calculations and indirectly of experiments, presented in Fig. 6e, 6f and Fig. 7c, 7d and given in the publication [45], respectively, proved the possibility of using a magnetic-electromagnetic passive-active suspension (Fig. 2, 3) as a complex support with quasi-zero stiffness. This is structurally feasible with some modification. With a vertical shaft arrangement shown in Fig. 8, this magnetic suspension can be considered as a whole as a passive-active vibration-damping and vibration-isolating complex support of either a load located above or a body suspended from below. Then the rotor is a non-rotating rod-shaft that holds the vibration-isolated load. In the case of structural or operational features of the supported or suspended body, the rod-shaft can rotate around the axis making a support a kind of a thrust bearing. The supported vibration damping and vibration isolation object weight is compensated by the bias current in the upper winding, i.e. it is provided by a certain constant difference of the average currents i_{c1} and i_{c2} in the upper and lower windings. This is taken into account in the control law (1) as a constant component of the bias currents. In addition to this feature, the force and stiffness characteristics with quasi-zero stiffness ranges, similar to those shown in Fig. 6-7, will be provided as before.

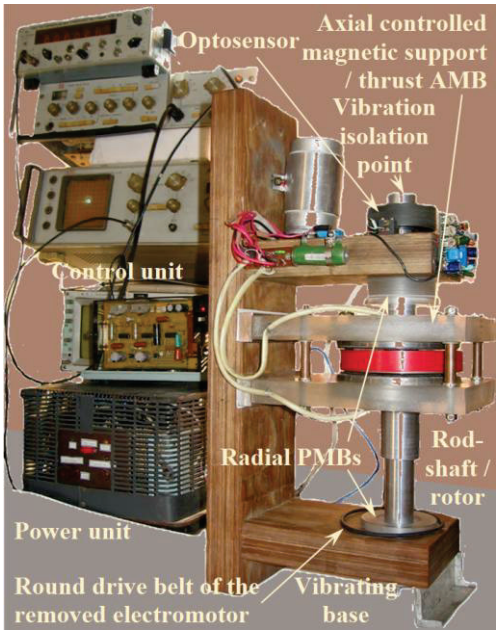

Fig. 8. Laboratory and experimental rig of passive-active vibration-damping and vibration-isolating complex magnetic support.

VI. Conclusion and Discussion

The paper considers approaches to analyzing the force and stiffness characteristics of a controlled AAMS using analytical and numerical methods. It was found that each of them allows determining the force characteristics with sufficient accuracy depending on the AAMS and CS parameters. Each of these approaches has its own features affecting accuracy. They can be used depending on the needs, required multivariance of calculations with different parameters, limited system and time resources, etc.

These approaches were applied to practical analysis of one of the AAMS variants with verification and validation of calculation models based on experimental data. The obtained results showed the possibility of providing the required force and stiffness characteristics with ranges of the desired quasi-zero stiffness by selecting applied control law parameters.

Based on the experimental rig of a combined passive-active magnetic-electromagnetic suspension of a model rotor, a variant of a vibration-damping and vibration-isolating complex magnetic support is considered. The proposed complex passive-active magnetic support, due to its controllability, can perform both the functions of vibration damping of the held object (device, instrument, equipment, dangerous goods or a person) and the functions of vibration isolation. In this case, vibration damping is ensured by controlled and managed resistance in the circuit of the EM windings or is implemented using special CS algorithms, which is now practically used in many rotary machines with rotors in AMBs. In turn, vibration-isolating properties are ensured by quasi-zero stiffness ranges implemented by the adopted control law. When it is necessary to isolate large and heavy objects from vibration, several complex supports can be used. Their synchronous operation is ensured by mutual connections in the electromagnetic AAMS CS.

***Abstract*— As a result of the analysis of existing studies, it was found that in the operation of a power supply system with a medium-capacity generator, insufficient attention is paid to the distribution of higher harmonic powers among system components. Using a microgrid model that includes a synchronous generator, an induction motor, a transformer, an external grid, and a current harmonic source, a series of experiments were conducted by introducing higher current harmonics and recording distortion levels and RMS power in individual branches. The analysis of the obtained results made it possible to es https://doi.org/10.5772/intechopen.87093lish regression relationships between harmonic currents and phase RMS power, as well as to assess their impact on power quality indicators, taking into account the type of load and the specific branch of the microgrid. It was found that in the studied setup, the third harmonic has the greatest impact on the transformer, while the fifth and seventh harmonics predominantly affect the generator and the electric motor..**

Keywords*— electric power, current and voltage harmonics, root mean square power, power quaility

I. Introduction

The intermittent operation of alternative energy sources, such as solar and wind [1], due to natural conditions, or the varying load levels during the operation of a diesel generator [2], affects the system—including voltage, frequency, and overall network performance. With the widespread integration of inverters, frequency converters, and other nonlinear loads, harmonic distortion is becoming an increasingly serious issue in distribution networks. Distorted supply voltage leads to distorted currents, while harmonic currents from consumers further degrade the power supply voltage quality. Advanced approaches such as power flow analysis in system branches [3, 4], assessment of voltage and current harmonic conditions [5, 6], and identification of harmonic source parameters [7, 8], help identify dominant sources of higher harmonics. However, they do not allow for determining the specific harmonic contribution level of each individual harmonic component, as these methods are based on generalized indicators.

II. Analysis Of Previous Research

In [9], the process of integrating a solar power plant into the energy system is considered for the purpose of planning solar power utilization. To effectively analyze voltage quality and calculate harmonic losses in a distribution network integrated with a solar power plant, a simplified scheme is used to model the harmonic impedance of key equipment such as transmission lines and transformers. Based on calculations of harmonic losses using measurement data, it was found that harmonic losses are primarily determined by harmonic current and account for approximately 0.6% of the total network losses.

Studies [10, 11] examine the impact of inverters on current and voltage harmonic distortion and propose a new impedance-harmonic relationship model for identifying harmonic resonance caused by inverters. The validity and effectiveness of the model are confirmed by its analytical simplicity and the fact that the frequency characteristics and coupling effects can be clearly observed for inverters with different control schemes.

Harmonic distortion in isolated synchronous generator machines [12] is more significant due to the limited short-circuit power level compared to the short-circuit power level at the buses of electrical networks. In addition, harmonic currents circulate only within a single loop between the generator and the load, and they cannot flow through the power grid bus, which contributes to increased harmonic distortion.

The impact of cable line length on the amplification of harmonic distortion during the operation of a solar power plant is discussed in [13]. The authors propose connecting the voltage source at the midpoint of the load node to reduce the influence of the cable on the system's capacitive current. It is established that with constant transmission capacity, the closer the connection is to the end of the plant's transmission line, the higher the level of harmonic distortion in the distribution network.

A similar issue is addressed in [14], which uses a methodology to study and define the limiting values of additional and cumulative harmonic distortion depending on the proximity of multiple harmonic sources to each other.

Thus, summarizing the above, it can be stated that in systems with power conversion devices used in certain generation complexes and/or consumer loads, harmonic current distortion is present. While the influence of higher harmonics on each individual system branch has been studied, the distribution of harmonic power among the branches has not been sufficiently addressed.

Objective of the study: To investigate the distribution of higher load current harmonics in a system with a limited-capacity generating unit and an external grid, based on their root mean square power, using the design of experiments method.

III. Materials And Results Of Research

Let us consider a diesel generator system complex [15] with a load and an external grid, structured as shown in Fig.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

1. The system consists of the following components: a diesel engine (DE), an excitation system (ES), a synchronous machine (SM), a linear load (LL), a nonlinear load (NLL), a transformer (TR), and the grid..

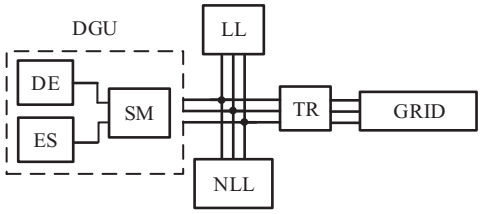

Fig. 1. Structural diagram of a diesel generator system connected to the grid

The synchronous generator is considered by some researchers both as a source of higher harmonic electromotive force , due to the specific characteristics of the machine's magnetic circuit, and as a consumer of higher harmonic currents generated by other harmonic sources [16].

By relating the values of X_{fv} i and and X_{kv} to frequency (for the coupling between stator and rotor windings), the slip for the v-th harmonic is introduced:

$$s_v = \frac{v \pm 1}{v} \tag{1}$$

Then the inductive reactance for the *v*-th harmonic is obtained:

$$X_{dv} = vX_l + \frac{1}{\frac{1}{vX_{ad}} + \frac{\sqrt{v \pm 1}}{vX_f} + \frac{\sqrt{v \pm 1}}{vX_k}} \tag{2}$$

where X_f - the corresponding stator resistance for the 1st harmonic; X_k - the rotor winding leakage reactance under strong skin effect conditions; X_{ad} - the mutual inductance reactance for the 1st harmonic; X_{fv} - the rotor winding leakage reactance under pronounced skin effect conditions*:* X_{kv} - the leakage reactance of the damper winding.

Asynchronous motors [17], at the synchronous rotational frequency corresponding to the *v*-th voltage harmonic with a frequency equal to vn_{syn}, have a slip S_v at the rotor speed frequency that is equal to the slip for the *v*-th harmonic:

$$S_v = \frac{vn_{syn} \pm (1-s)}{vn_{syn}} = \frac{v \pm (1-s)}{v} \tag{3}$$

Assuming a strong manifestation of the skin effect, $(R_{kv} = R_k\sqrt{v})$ the total impedance of the asynchronous motor for the v-th harmonic is determined as:

$$Z_v = \sqrt{R_{kv}^2 + X_{kv}^2} = \sqrt{v^2 X_k^2 + vR_k^2} \approx vX_k \approx vZ_k \tag{4}$$

where R_k , X_k , Z_k - the active, the reactive an the total short-circuit impedance of the asynchronous motor, respectively.

The impedance of a 6–10 kV transformer, whose load consists of asynchronous motors, can be represented in the equivalent circuit for higher harmonics as the sum of the short-circuit impedances of the transformer and the asynchronous motors:

$$X_{u,Tv} = vX_{k,T} + \frac{vU_{nom}^2}{0,75k_S S_{nom}} \tag{5}$$

where $X_{k,T}$ - the short-circuit impedance of the transformer at the industrial frequency, Ohms;, U_{nom} , S_{nom} - the rated voltage, in kV, of the high-voltage winding (6–10 kV), the rated power of the transformer, in MVA; k_S - the starting current multiple of the equivalent asynchronous motor (on average, k_S = 5.5), which forms the load of the transformer; 0,75 - a coefficient that accounts for the transformer's loading level.

Using the indicators provided in [18], a method was proposed for determining the components of power that reflect specific types of power distortion in the transmission line, namely.

Current distortion power:

$$D_I = U_{rms.h} I_{rms.h} = U_{rms.1} I_{rms.1} THD_I \tag{6}$$

Voltage distortion power:

$$D_U = U_{rms.h} I_{rms.1} = U_{rms.1} I_{rms.1} THD_U \tag{7}$$

Total harmonic power:

$$S_H = U_{rms.h} I_{rms.h} = U_{rms.1} I_{rms.1} THD_U THD_I \tag{8}$$

where THD_U , THD_I - Total Harmonic Distortion coefficient of voltage and current; $U_{rms.1}$, $I_{rms.1}$ - root mean square (RMS) values of current and voltage of the fundamental harmonic; $U_{rms.h}$, $I_{rms.h}$ - RMS values of current and voltage of the higher harmonicsк..

The specified powers are derived from the total apparent power represented as follows:

$$\begin{aligned} S^2 &= \left(U_{rms} I_{rms}\right)^2 = \\ &= \left(U_{rms.1}^2 + U_{rms.h}^2\right)\left(I_{rms.1}^2 + I_{rms.h}^2\right) = \\ &= \left(U_{rms.1} I_{rms.1}\right)^2 + \left(U_{rms.1} I_{rms.h}\right)^2 + \\ &+ \left(U_{rms.h} I_{rms.1}\right)^2 + \left(U_{rms.h} I_{rms.h}\right)^2 . \end{aligned} \tag{9}$$

But in a similar way, in this case, it is possible to use the RMS values of the current $I_{rms.h}$ and voltage harmonics $U_{rms.h}$ instead of the RMS values of the higher current and I_h voltage harmonic U_h. However, such an option is not considered in [18].

Another option for power estimation in AC circuits with nonsinusoidal waveforms is used in [19, 20]. The authors justify the feasibility of using the root mean square (norm) of the instantaneous power.

$$\|p\| = P_{rms} = \sqrt{\frac{1}{T}\int_{t_0}^{t_0+T} p^2 dt} = \sqrt{\frac{1}{T}\int_{t_0}^{t_0+T} (ui)^2 dt} \quad (10)$$

where p is the instantaneous power; u and i are the instantaneous voltage and current; t_0 is the time corresponding to the start of measurement; and T is the period of the alternating voltage

Let us consider the case when the insntantaneous voltage and current consist of a fundamental component and several higher harmonics. Since the spectrum of higher harmonics is infinite, we will limit the analysis to the following:

$$u = u_1 + u_3 + u_5 \quad (11)$$

Then the instantaneous power is defined as follows:

$$\begin{aligned} p = ui &= (u_1 + u_3 + u_5)(i_1 + i_3 + i_5) = \\ &= u_1 i_1 + u_3 i_3 + u_5 i_5 + u_1 i_3 + \\ &+ u_1 i_5 + u_3 i_1 + u_3 i_5 + u_5 i_1 + u_5 i_3. \end{aligned} \quad (12)$$

As noted in [18], the frequency of power harmonics is formed as the sum and difference of the voltage and current harmonic frequencies, in this case:

$$\begin{aligned} p_0 &= (u_1 i_1)_{1-1} + (u_3 i_3)_{3-3} + (u_5 i_5)_{5-5}; \\ p_2 &= (u_1 i_1)_{1+1} + (u_1 i_3)_{1-3} + (u_3 i_1)_{3-1} + \\ &+ (u_3 i_5)_{3-5} + (u_5 i_3)_{5-3}; \\ p_4 &= (u_1 i_3)_{1+3} + (u_3 i_1)_{3+1} + \\ &+ (u_1 i_5)_{1-5} + (u_5 i_1)_{5-1}; \\ p_6 &= (u_3 i_3)_{3+3} + (u_1 i_5)_{1+5} + (u_5 i_1)_{5+1}; \\ p_8 &= (u_3 i_5)_{3+5} + (u_5 i_3)_{5+3}; \\ p_{10} &= (u_5 i_5)_{5+5}. \end{aligned} \quad (13)$$

Thus, in this case, the root mean square value of power is formed by taking into account all components of the instantaneous power and the combinations of current and voltage frequencies:

$$P_{rms} = \sqrt{\frac{1}{T}\int_{t_0}^{t_0+T} (p_0 + p_2 + p_4 + p_6 + p_8 + p_{10})^2 dt} \quad .(14)$$

To study power distribution and the impact of higher harmonic currents, the well-known model [21] was adapted in Matlab/Simulink (Fig. 2). It consists of the following blocks: a synchronous machine with a nominal frequency of f_{nom} = 50 Hz, nominal line voltage U_{nom} = 400 V, nominal apparent power S_{nom} = 31.3 kVA, and rotational speed PRM = 1500 rpm (SM 31.3 kVA); the excitation voltage (Vtref(pu)) and the mechanical power of the synchronous generator Pm are set as constant values, obtained based on preliminary calculations using the Simulink "Load Flow" utility; an asynchronous machine with a nominal frequency of f_{nom} = 50 Hz, nominal line voltage U_{nom} = 400 V, nominal power P_{nom} = 15 kW, and rotational speed PRM = 1500 rpm (AM 15 kW), to which a torque input block (Torque (N·m) is connected; and an additional load block with P_{nom} = 3 kW (3 kW Load), A transformer block with a high-voltage side rated at U_{HV} = 10 kV and a low-voltage side rated at U_{LV} = 400 V, with a nominal apparent power of S_{nom} = 60 kVA (Transformer 10 kV/400 V, 60 kVA); an external grid block with a nominal voltage of U_{nom} = 10 kV and a nominal apparent power of S_{nom} = 10 MVA (10 kV 10 MVA); and an external grid load block with a nominal active power of P_{nom} = 5 MW (5 MW Load). The harmonic injection block (Harmonic I) introduces higher-order harmonics into the phases and consists of three current source blocks generating the 3rd, 5th, and 7th harmonics, along with a parallel-connected resistor (see Fig. 3). The system also includes current and voltage measurement blocks: at the synchronous machine branch (Three-Phase V-I SG), at the asynchronous machine branch (Three-Phase V-I AM), at the external grid branch (Three-Phase V-I TV), and a measurement unit for collecting the acquired data (Measurement Unit)

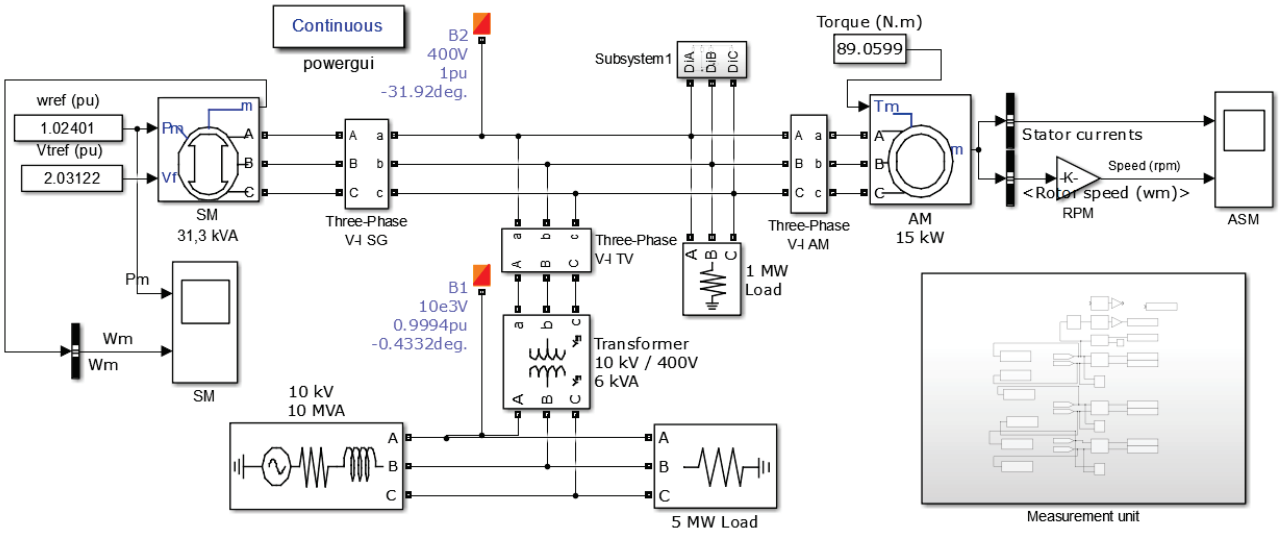

Fig. 2. Mathematical model of the diesel generator unit

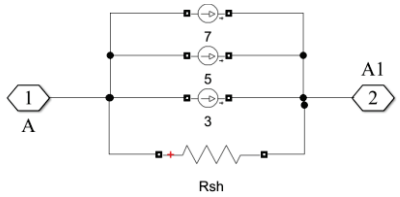

Fig. 3. Harmonic generation block of the nonlinear load current

To study the impact of the current harmonic level on the distribution of current distortion levels and power estimation across the branches of the analyzed system, the method of experimental design is applied.

Using the experimental design method [22], the conditions for analyzing the model are defined based on the indicators of current distortion in the model branches and the root mean square (RMS) phase power. The conditions, expressed as the magnitudes of the injected harmonic current components, are summarized in Table I, where the amplitude of the fundamental harmonic is 62 A for all experiments. The experimental design was conducted using the Statgraphics software package.

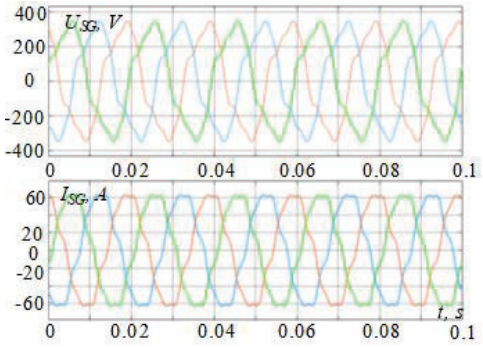

Fig. 4. Time-domain diagrams of currents and voltage in the synchronous generator branch

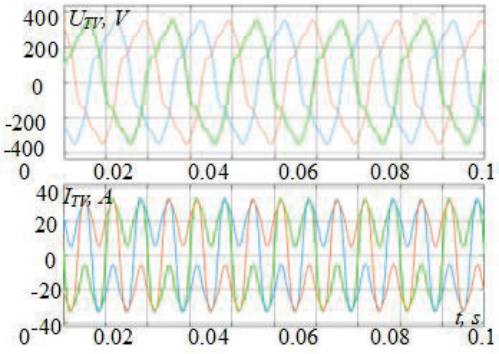

Fig. 5. Time-domain diagrams of currents and voltages in the transformer branch

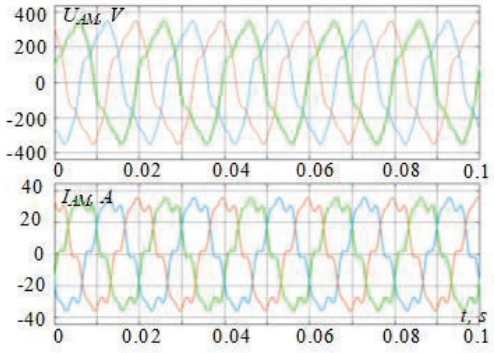

Fig. 6. Time-domain diagrams of currents and voltages in the asynchronous motor branch

Based on the data obtained from the experiments, regression model equations were calculated for each branch of the system using the Statgraphics software package. It is important to note that the currents are considered in per-unit values. $I'' = I_h / I_{fund}$.

For the total harmonic distortion (THD) of the current in the synchronous machine branch, the model shows that all three harmonics—the third, fifth, and seventh—have a positive linear contribution to the formation of harmonic current distortion in the synchronous machine. The influences of the fifth and seventh harmonics are the most significant, while the third harmonic also exhibits an additional nonlinear effect.

$$THD_{IS.G} = -0,0117661 + 0,00309106 \cdot I_3'' + \\ +0,00343581 \cdot I_5'' + \\ +0,00343581 \cdot I_7'' - 0,000103035 \cdot I_3''^2 \quad (15)$$

For the root mean square (RMS) phase power of the synchronous machine branch, the model indicates that the largest contribution to the increase comes from the third harmonic, both in linear and quadratic forms. The influence of the fifth and seventh harmonics is more complex: they linearly reduce the value but exhibit some compensating effects through quadratic and interaction (pairwise) terms.

$$PRMS_{ph.SG} = 7392,78 + 18,4613 \cdot I_3'' - \\ -0,793556 \cdot I_5'' - 0,890368 \cdot I_7'' + \\ +0,204227 \cdot I_3''^2 + 0,1288 \cdot I_3'' \cdot I_5'' - \\ -0,0212 \cdot I_3'' \cdot I_7'' + 0,0521191 \cdot I_5''^2 + 0,0254 \cdot I_5'' \cdot I_7'' \quad (16)$$

For the total harmonic distortion (THD) of the current phase in the transformer branch, the regression equation indicates that the third harmonic has the greatest impact on the overall harmonic distortion of the transformer current, while the fifth and seventh harmonics exert a significantly weaker linear influence. Interactions between the harmonics have a compensating effect, which slightly reduces the predicted THD value when multiple harmonics act simultaneously.

$$THD_{I.TV} = 0,0156275 + 0,0380441 \cdot I_3'' + \\ +0,00169802 \cdot I_5'' + 0,00169802 \cdot I_7'' - \\ -0,0002 \cdot I_3'' \cdot I_5'' - 0,0002 \cdot I_3'' \cdot I_7'' \quad (17)$$

For the root mean square (RMS) phase power of the transformer branch, the model demonstrates that the main contribution to the variation in RMS power is due to the third harmonic, whose effect is distinctly negative and nonlinear. The seventh harmonic has a minor negative effect.

$$PRMS_{ph.TV} = 2955,38 - 122,324 \cdot I_3'' - \\ -0,405468 \cdot I_7'' + 0,185911 \cdot I_3''^2 \quad (18)$$

For the total harmonic distortion (THD) of the current phase in the asynchronous machine branch, the model indicates that the third, fifth, and seventh harmonics have a positive influence on the overall harmonic current distortion. However, when high values of both the fifth and seventh harmonics are present simultaneously, their combined effect is partially compensated by a negative interaction term.

$$THD_{I.AM} = -0,0430238 + 0,00181077 \cdot I_3'' + \\ +0,0100405 \cdot I_5'' + 0,0100405 \cdot I_7'' - 0,0003 \cdot I_5'' \cdot I_7'' \quad (19)$$

For the root mean square (RMS) phase power of the asynchronous machine branch, the model accurately accounts for both the individual and interaction effects of the third, fifth, and seventh order harmonics on the RMS power of the asynchronous machine. The third harmonic has the greatest influence, both in linear and quadratic forms.

$$PRMS_{ph.AM} = 3952,42 + 23,1392 \cdot I_3'' + \\ +0,718265 \cdot I_5'' + 0,384424 \cdot I_7'' + \\ +0,012908 \cdot I_3''^2 - 0,2102 \cdot I_3'' \cdot I_5'' - \\ -0,0055 \cdot I_3'' \cdot I_7'' + 0,00215359 \cdot I_5''^2 - \\ -0,0302 \cdot I_5'' \cdot I_7'' - 0,0122101 \cdot I_7''^2 \quad (20)$$

Using the data obtained with the Statgraphics software package, the following calculations were performed: the coefficient of determination R^2, which shows the degree of dependence of the variable on the variation of independent variables, approaches 100% in all cases. The Pareto-adjusted statistic R^2_P, , which accounts for the number of independent variables, also has high values, confirming the stability of the models regardless of their complexity. The standard error of estimation $A_{e.e}$ which characterizes the deviation between actual and predicted values, is low for all models. The mean absolute error $AA_{e.e}$ – which also characterizes the deviation between actual and predicted values, is low for all models. The Durbin-Watson statistic *DWS* – used to detect autocorrelation of residuals, exceeds 5% in most cases and is below 5% in only one case; overall, the system exhibits only minor autocorrelation. The results of these calculations are summarized in Table II.

TABLE II. RESULTS OF THE PERFORMED CALCULATIONS

	R^2, %	R^2_P, %	$A_{e.e}$	$AA_{e.e}$	*DWS*, %
$THD_{IS.G}$,	99,57	98,94	0,0025	0,0013	<5
$PRMS_{ph.SG}$	99,99	99,99	0,7222	0,3580	>5
$THD_{I.TV}$	99,98	99,95	0,0033	0,0017	>5
$PRMS_{ph.TV}$	99,99	99,99	2,776	1,350	>5
$THD_{I.AM}$	99,86	99,65	0,0026	0,013	>5
$PRMS_{ph.AM}$	99,99	99,99	0,53	0,28	>5

CONCLUSIONS

On the synchronous generator branch, the third higher harmonic current has the least influence on total harmonic distortion, yet it has the greatest impact on the phase root mean square (RMS) power, although the actual change in power is small. The influence of the fifth and seventh higher harmonics slightly increases; meanwhile, the phase RMS power slightly increases with the fifth harmonic but slightly decreases with the seventh harmonic. The correlation between consecutive values is less than 5.0%, indicating possible serial correlation at a 5.0% significance level, while there is no evidence of sequential autocorrelation in the residuals of the phase RMS power at the 5.0% significance level.

On the transformer branch, the third higher harmonic has the greatest impact. An increase in the current value of the third higher harmonic corresponds to an increase in distortion and a simultaneous decrease in the phase RMS power. The values of the fifth and seventh higher harmonic currents also increase, but no effect on power is observed. The correlation between consecutive values exceeds 5.0%, so there is no indication of sequential autocorrelation in the residuals, both for overall harmonic distortion and for the phase RMS power.

On the asynchronous machine branch, the influence of the third higher harmonic on total harmonic distortion does not change significantly, but its effect on phase RMS power is considerable. The fifth and seventh harmonics increase, but their influence on phase RMS power slightly decreases. The correlation between consecutive values is less than 5.0%, indicating possible serial correlation at the 5.0% significance level, while there is no evidence of sequential autocorrelation in the residuals of the phase RMS power at the 5.0% significance level.

***Abstract*—This paper provides a physical justification for the use of the power factor and its interpretation in the general case for single-phase electrical networks and loads. A mathematical proof is provided for the power factor formula under arbitrary voltage and current waveforms. An alternative metric — the Active Loss Factor — is proposed, along with its mathematical rationale and interpretation. Expressions are presented for calculating the integral values of both the power factor and the Active Loss Factor over an extended time period. An example of calculating the integral value of the Active Loss Factor over a 24-hour period is provided for a single-phase network with two types of loads.**

Keywords—power factor, energy efficiency, active loss factor, electric network

I. Introduction

Electric energy losses have been relevant since the advent of the first power grids and remain critical today [1], [2]. Numerous studies examine how the nature of consumption influences technical losses and power quality [3], [4]. IEEE Std 1459 also formalizes these relationships [5].

Improving energy efficiency and power quality requires a clear understanding of the specific causes of losses and concrete measures to mitigate them. Key characteristics that increase technical losses include reactive behavior, harmonic distortion (nonsinusoidal conditions), unbalance, and nonstationarity.

Accordingly, ensuring favorable modes of power transmission and consumption requires not only identifying these issues but also determining how to address them.

Aim of the research. Our goal is to

(i) provide a compact, physically grounded derivation of the general power-factor expression valid for arbitrary waveforms;

(ii) introduce the Active Loss Factor (AF) as an alternative, loss-centric metric that directly quantifies the copper-loss penalty; and

(iii) derive integral, time-aggregated formulas enabling fair comparison of nonstationary consumption regimes and illustrate the approach on a day-long example.

Contributions and novelty. We recast the power factor (PF) around a clear physical optimum, introduce AF—a loss-based metric—and derive time-aggregated (integral) formulations with evidence that make the assessment robust for real-world, nonstationary single-phase operation. Note: AF here is distinct from the "active power loss factor" used as a planning coefficient and from the market "Average Loss Factor (ALF)."

II. Background: Classical Definition of Power Factor

One of the most widely used approaches for evaluating the energy efficiency of equipment or operating modes in modern research is the use of the power factor [1-4],[6]. According to IEEE Std 1459 [5]

$$PF = P/S,$$

where P - active power, $S = U_{RMS} I_{RMS}$ - apparent power, U_{RMS} and I_{RMS} - RMS voltage and current. It includes an interpretive note that PF can be viewed as the ratio between the active energy actually delivered to the load and the maximum active energy that could be delivered under the same line I²R loss level. But, in general, IEEE Std 1459 focuses on measurement-oriented definitions and a taxonomy of power-factor–related indices (e.g., true PF, displacement PF, distortion factor) under sinusoidal and nonsinusoidal conditions. It does not provide detailed physical derivations, optimization-based interpretations, or explicit optimality conditions for PF; such aspects fall outside the scope of a measurement standard. In addition classical PF have next limitations:

Not additive / not time-robust. PF of combined loads is not a weighted average of individual PFs; likewise, simple time-averaging of PF over operating intervals is not meaningful.

Not loss-direct. Copper (I²R) losses scale with I^2_{RMS}, not with PF. Thus equal PF does not imply equal feeder losses, and PF can improve while losses increase.

III. Power Factor Justification

Consider the evaluation of the efficiency of energy transfer processes in a separate phase in the general case, at non-sinusoidal voltage and non-sinusoidal current.

Fig. 1 shows the cross-section of the measurement M and the power distribution in a single-phase network. In this case, the loss of power is denoted as P_{LS}, and the consumed power as P_{LD}. The power transmission network is characterized by inductive L and active r resistances, which are equally distributed between the two conductors. The power source in the network is described by the EMF $e(t)$, and the measured load voltage across the cross section is $u(t)$. The load resistance $R(t)$ is generally nonlinear and nonstationary.

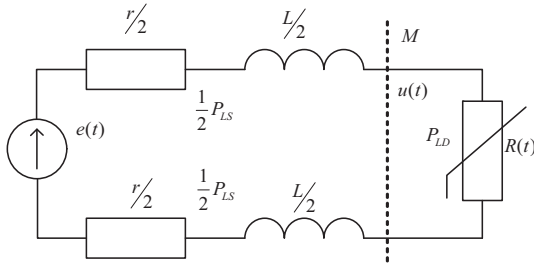

Fig. 1 Measurement of losses and power in a single-phase network

Energy efficiency assessment is performed by comparing the active power consumed by the current consumer with the power of some "standard" ideal consumer

$$K_{EFF} = \frac{P_{LD}}{P_{MAX}}, \tag{1}$$

where P_{MAX} represents the power consumed by the ideal consume, provided that the same level of power losses is maintained P_{LS}.

Fig. 2 shows the physical meaning of this comparison. Two systems $S1$ and $S2$ are compared, in which the power losses on the active impedance of the power supply system are equal and amount to $P_{LS1} = P_{LS2} = P_{LS}$. The condition is also the equality of the voltage on the load buses $u_{LD1}(t) = u_{LD2}(t) = u_{LD}(t)$. At the same time, the voltage or the electromotive force (EMF) in the systems $e_{S1}(t)$ and $e_{S2}(t)$ may differ, as well as the inductive component of the network resistance L_{S1}, L_{S2}. Thus, the system $S2$ is designed so that the load power is maximized with equal transmission losses and identical voltage at the load buses. This obviates the need to account for unknown system parameters of the power system and the transmission system. For a complete calculation, the parameters that can be measured in the cross-section M are sufficient [3].

The conditions for achieving P_{MAX} can be determined in two steps. For any $u(t)$ and $i(t)$, one can perform a Fourier series expansion

$$u(t) = \sum_{k=0}^{\infty} U_{m,k} sin(k\omega t + \phi_k),$$
$$i(t) = \sum_{h=0}^{\infty} I_{m,h} sin(h\omega t + \psi_h), \tag{2}$$

where $U_{m,k}$, $I_{m,h}$, ϕ_k, ψ_h – are the amplitude values and phases of the relevant voltage and current harmonics, k and h – are integers. Given $U_{m,k}$ and ϕ_k are known, determine $I_{m,h}$ and ψ_h to obtain the extremum of the power function

$$P = \frac{\omega}{2\pi} \int_0^{\frac{\omega}{2\pi}} p(t)\,dt \text{, where} \tag{3}$$

$$p(t) = \sum_{k=1}^{\infty}\sum_{h=1}^{\infty}\left[U_{m,k} sin(k\omega t + \phi_k) I_{m,h} sin(h\omega t + \psi_h)\right] \tag{4}$$

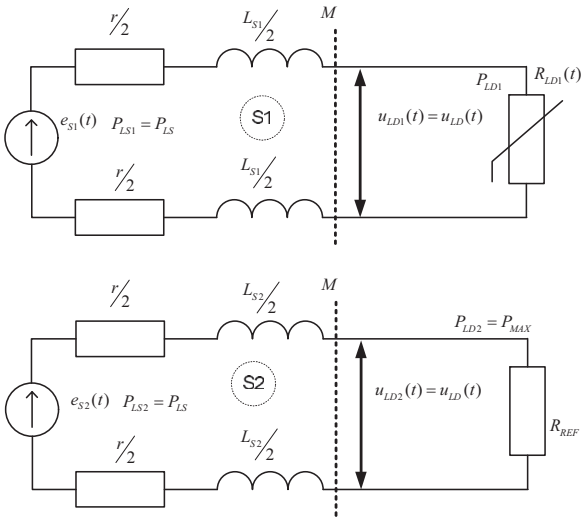

Fig. 2 Comparison of delivered load power under equal distribution-line I²R losses

To simplify further calculations, a zero constant component is assumed., $U_{m,0} = 0$ and $I_{m,0} = 0$.

The first step is to find the value of ψ_h, which corresponds to the extremum of function (3). By integrating

$$\int p(t)\,dt = \begin{cases} \sum_{k=1}^{\infty}\left[D_1 t - D_2\right], k = h \\ \sum_{h=1}^{\infty}\sum_{k=1}^{\infty}\left[D_3 - D_4\right], k \neq h \end{cases},$$

$$D_1 = \frac{I_{m,k} U_{m,k} cos(\psi_k - \phi_k)}{2},$$

$$D_2 = \frac{I_{m,k} U_{m,k} sin(\psi_k + \phi_k + 2\omega k t)}{4\omega k},$$

$$D_3 = \frac{I_{m,h} U_{m,k} sin(\psi_h - \phi_k + \omega(k-h)t)}{2\omega(k-h)},$$

$$D_4 = \frac{I_{m,h} U_{m,k} sin(\psi_h + \phi_k + \omega(k+h)t)}{2\omega(k+h)},$$

after setting the limits

$$\int_0^{2\frac{\pi}{\omega}} p(t)\,dt = \sum_{k=1}^{\infty}\left[\frac{I_{m,k} U_{m,k} \pi cos(\psi_k - \phi_k)}{\omega}\right], \tag{5}$$

with integers k and h

$$\sum_{k=1}^{\infty}\left[\frac{\left(I_{m,k}U_{m,k}cos\left(\psi_k-\phi_k\right)\right)}{2}t-\frac{\left(I_{m,k}U_{m,k}sin\left(\psi_k+\phi_k+2\omega kt\right)\right)}{4\omega k}\right]\Bigg|_0^{2\frac{\pi}{\omega}}=$$

$$=\sum_{k=1}^{\infty}\left[\frac{I_{m,k}U_{m,k}\pi cos\left(\psi_k-\phi_k\right)}{\omega}+\frac{I_{m,k}U_{m,k}\left(sin\left(\psi_k+\phi_k\right)-sin\left(\psi_k+\phi_k+4\pi k\right)\right)}{4\omega k}\right]=$$

$$=\sum_{k=1}^{\infty}\left[\frac{I_{m,k}U_{m,k}\pi cos\left(\psi_k-\phi_k\right)}{\omega}\right]$$

and

$$\sum_{h=1}^{\infty}\sum_{k=1}^{\infty}\left[D_3-D_4\right]\Bigg|_0^{2\frac{\pi}{\omega}}=\sum_{h=1}^{\infty}\sum_{k=1}^{\infty}\left[D_5+D_6\right]=0\,, \tag{6}$$

$$D_5=\frac{I_{m,h}U_{m,k}\left(sin\left(\psi_h-\phi_k\right)-sin\left(\psi_h-\phi_k+2\pi\left(h-k\right)\right)\right)}{2\omega\left(k-h\right)},$$

$$D_6=\frac{I_{m,h}U_{m,k}\left(sin\left(\psi_h+\phi_k\right)-sin\left(\psi_h+\phi_k+2\pi\left(h+k\right)\right)\right)}{2\omega\left(k+h\right)}.$$

To find the extremes, one need to differentiate the function for each of the desired variables ψ_k,

$$MAX\sum_{k=0}^{\infty}\left[\frac{I_{m,k}U_{m,k}\pi cos\left(\psi_k-\phi_k\right)}{\omega}\right]=\sum_{k=0}^{\infty}MAX\,\frac{I_{m,k}U_{m,k}\pi cos\left(\psi_k-\phi_k\right)}{\omega}.$$

Then find the roots

$$\frac{\partial}{\partial\psi_k}\left[\frac{I_{m,k}U_{m,k}\pi cos\left(\psi_k-\phi_k\right)}{\omega}\right]=\frac{I_{m,k}U_{m,k}\pi sin\left(\phi_k-\psi_k\right)}{\omega}=0\,. \tag{7}$$

An infinite number of extrema occur at the points $\psi_k=\varphi_k\pm\pi n$, where n is an integer. Even $n=0,\pm2,\pm4$, ... and 0 correspond to the points of maximum, and odd $n=\pm1,\pm3,\pm5$, ... – correspond to the points of minimum. Thus, the maximum occurs at the points

$$\psi_k=\varphi_k\,, \tag{8}$$

when the phase of the current harmonic coincides with the phase of the same voltage harmonic, regardless of the amplitude of this harmonic.

The second stage is $I_{m,h}$. When the phases of the corresponding harmonics are coincident, the average power over the period of the fundamental harmonic from (3) is obtained:

$$P=\frac{\omega}{2\pi}\int_0^{\frac{\omega}{2\pi}}p\left(t\right)dt=\frac{\omega}{2\pi}\sum_{k=1}^{\infty}\left[\frac{I_{m,k}U_{m,k}\pi}{\omega}\right]=\sum_{k=0}^{\infty}\left[\frac{I_{m,k}U_{m,k}}{2}\right] \tag{9}$$

Next, the ratio of the amplitude values of the harmonic components of the current must be determined. Accordingly, this can be expressed as:

$$I_{RMS}=\frac{1}{\sqrt{2}}\sqrt{\sum_k I_{m,k}^2}\,, \tag{10}$$

$$P=\frac{1}{2}\sum_k\left(U_{m,k}I_{m,k}\right),\ k=1,2,3,... \tag{11}$$

Expressing the amplitudes of higher harmonic components via the amplitude of the fundamental harmonic yields:

$$I_{m,k}=K_kI_{m,1}, \tag{12}$$

$k=1,2,3,\ldots$, the coefficient corresponding to the first harmonic. $K_1=1$.

For an arbitrary set of harmonics, it is possible to write:

$$2I_{RMS}^2=\sum_k K_k^2I_{m,1}^2 \tag{13}$$

$$P=\frac{1}{2}\sum_k\left(U_{m,k}K_k\sqrt{\frac{2I_{RMS}^2}{\sum_n K_n^2}}\right), \tag{14}$$

where $n=1,2,3,...$

Differentiating by K_k results in the following system of equations:

$$\frac{\partial P}{\partial K_k}=\frac{U_{m,k}}{2}\sqrt{\frac{2I_{RMS}^2}{\sum_n K_n^2}}-\frac{K_kI_{RMS}^2\sum_n\left[K_nU_{m,n}\right]}{\sum_n K_n^2}\sqrt{\frac{\sum_n K_n^2}{2I_{RMS}^2}}\,, \tag{15}$$

and equating the right-hand parts to (15):

$$\frac{\partial P}{\partial K_k}=I_{RMS}^2\frac{\left(U_{m,k}\sum_n K_n^2-K_k\sum_n\left[K_nU_{m,n}\right]\right)}{\sum_n K_n^2}\sqrt{\frac{\sum_n K_n^2}{2I_{RMS}^2}}=0 \tag{16}$$

The solution looks as:

$$K_k=\frac{U_{m,k}\sum_{n,n\neq k}K_n^2}{\sum_{n,n\neq k}\left[K_nU_{m,n}\right]} \tag{17}$$

and the solution of the system will be:

$$K_k=\frac{U_{m,k}}{U_{m,1}}, \tag{18}$$

Substituting yields:

$$I_{m,k}=\frac{U_{m,k}}{U_{m,1}}I_{m,1}\,, \tag{19}$$

this implies that the amplitudes of current harmonics should be proportional to the voltage amplitudes of the same harmonics, which is consistent with the conclusions made in [3]. Substituting the results of (8) and (19) into (3) and (4), yields the following result:

$$P_{MAX}=U_{RMS}I_{RMS}\,, \tag{20}$$

where U_{RMS} and I_{RMS} – are the root-mean-square (RMS) (effective values of voltage and current).

This implies that:

$$U_{RMS}=\sqrt{\frac{\omega}{2\pi}\int_0^{\frac{2\pi}{\omega}}u^2(t)dt}\,, \tag{21}$$

$$I_{RMS}=\sqrt{\frac{\omega}{2\pi}\int_0^{\frac{2\pi}{\omega}}i^2(t)dt}\,, \tag{22}$$

accordingly:

$$K_{EFF}=\frac{P_{LD}}{U_{RMS}I_{RMS}}=PF\,. \tag{23}$$

Therefore, the resulting expression matches the general definition of the power factor in the general case. In other words, the power factor reflects how many times the load power is less than the maximum possible power at the same voltage and the same level of losses in the active resistance of the current conductor.

It should be noted that the considered model is the simplest and takes into account only losses in the active resistance of current conductors. Other types of technical losses and factors that affect them are not taken into account. In some works, modified formulas are considered, which, for example, take into account the so-called skin effect. In addition, the list of technical loss factors can also include losses in magnetically conductive elements, losses in parasitic capacitance currents of power transmission lines, corona losses, electromagnetic radiation, etc. However, all these factors are considered secondary. First, the real amount of electricity losses caused by them is much smaller compared to losses in the active resistance of current conductors. Secondly, such factors largely depend on the specific configuration of the network, the equipment used and the connection point. Attempting to take them into account requires a large amount of additional information, significantly complicates the calculations, and, at the same time, yields no significant practical advantage. The standard method for calculating the power factor can be carried out at any cross-section with the possibility of measuring current and voltage.

Thus, the advantages of such an approach include its versatility and ease of implementation. The necessary mathematical apparatus can be implemented on the basis of almost any microprocessor device, both in the format of special measuring equipment and in the structure of a standard electricity meter. The measured parameters coincide with the parameters required for a standard metering system. Eliminating the necessity to build any complex system covering several points of the power system, and information about the scheme and parameters of the electrical network and the equipment connected to it is also not required.

The main disadvantage of the approach is that the measured power factor, as can be understood from Fig. 2, depends not only on the load characteristics but also on the impedance of the power system. Thus, in most cases, the system resistance is 2-3 orders of magnitude lower than the load resistance, and, accordingly, this factor can be neglected. However, in some cases it can significantly affect the conclusions. In addition, as previously noted above, the approach does not fully account for actual technical losses.

IV. Active Loss Factor

An alternative approach also follows from the formulation of the problem. The second option is to compare the magnitude of the power losses and obtain the loss coefficient

$$K_L = \frac{P_{LS}}{P_{LS,MIN}}, \tag{24}$$

where $P_{LS,MIN}$ – is the minimum value of losses, for a load with equal power consumption. Fig. 3 shows an explanation of the physical meaning. Also compared are two systems $S1$ and $S2$, in which the load power coincides $P_{LD1} = P_{LD2} = P_{LD}$, as does the voltage on its buses $u_{LD1}(t) = u_{LD2}(t) = u_{LD}(t)$, but the power losses on the active resistance r of the power supply system $S2$ are minimal, and are equal to $P_{LS2} = P_{LS,MIN}$.

$$K_L = \frac{rI_{RMS}^2}{rI_{RMS,MIN}^2} = \frac{I_{RMS}^2}{I_{RMS,MIN}^2} \tag{25}$$

$$I_{RMS,MIN} = \frac{P_{LD}}{U_{RMS}} \tag{26}$$

$$K_L = \frac{I_{RMS}^2 U_{RMS}^2}{P_{LD}^2} = \frac{1}{PF^2} \tag{27}$$

Thus, the loss ratio is inversely proportional to the square of the power factor. For ease of use, it is proposed to call the obtained value the active loss ratio and denote it as AF:

$$AF = \frac{I_{RMS}^2 U_{RMS}^2}{P^2} = \frac{1}{PF^2} \tag{28}$$

This is due to the fact that the coefficient LF in modern scientific works refers to either the load factor [7] or the loss factor, which indicates the percentage of energy losses in the electrical network [8].

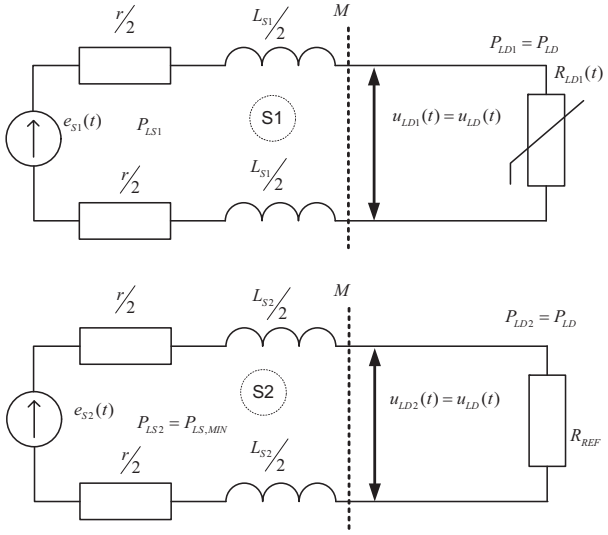

Fig. 3 Comparison of the magnitude of losses on the active resistance of the transmission system

It should be noted that the power factor is currently widely used in scientific works [1-4,6,9-15], engineering calculations [16,17] and even standards [5]. But a slightly different interpretation of this coefficient is generally accepted, in particular the physical meaning. It is calculated, most often, as the ratio of consumed power to full (or apparent) power, the latter being measured in volt-amperes and not considered active. There is also without physical justification or stated limitations [5].

The physical meaning of the Active Loss Factor seems to be more indicative and informative in comparison with the power factor. Thus, AF indicates how many times higher the I^2R losses in the line's series resistance are than the theoretical minimum for the same load power and voltage. In addition, the Active Loss Factor is more convenient when calculating the integral assessment of the energy efficiency of electricity consumption.

The proposed approach, in conjunction with the Active Loss Factor, enables an integral assessment of energy efficiency over a given time interval. Under the assumption of constant power, the following expression can be formulated:

$$K_{L,T} = \frac{W_{LS}}{W_{LS,MIN}} = \frac{P_{LS} \cdot T_F}{P_{LS,MIN} \cdot T_F} = \frac{rI_{RMS}^2 \cdot T_F}{rI_{RMS,MIN}^2 \cdot T_F} = AF_T, \quad (29)$$

where W_{LS} – is the energy loss in the time interval T_F, and $W_{LS,MIN}$ – is the minimum energy loss in the same interval. Given that:

$$AF = \frac{I_{RMS}^2 U_{RMS}^2}{P^2} = \frac{I_{RMS}^2}{I_{RMS,MIN}^2}, \quad (30)$$

from

$$I_{RMS,MIN}^2 = \frac{I_{RMS}^2}{AF}. \quad (31)$$

than

$$W_{LS,MIN} = rI_{RMS,MIN}^2 \cdot T_F = r\frac{I_{RMS}^2}{AF} \cdot T_F \quad (32)$$

Under variable load conditions, the time domain is discretized into intervals wherein power consumption is assumed to remain constant $T_F = T_1 + T_2 + ... + T_N$. This facilitates the derivation of the following expression:

$$AF_T = \frac{\sum\limits_{i=1..N} W_{LS,i}}{\sum\limits_{i=1..N} W_{LS,MIN,i}} = \frac{\sum\limits_{i=1..N} rT_i I_{RMS,i}^2}{\sum\limits_{i=1..N} \frac{rT_i I_{RMS,i}^2}{AF_i}} = \frac{\sum\limits_{i=1..N} T_i I_{RMS,i}^2}{\sum\limits_{i=1..N} \frac{T_i I_{RMS,i}^2}{AF_i}} \quad (33)$$

But if expressing the value from (28) the value of I_{RMS}^2

$$I_{RMS}^2 = \frac{AF \cdot P^2}{U_{RMS}^2} \quad (34)$$

and substitute it into (33), yields:

$$AF_T = \frac{\sum\limits_{i=1..N} T_i I_{RMS,i}^2}{\sum\limits_{i=1..N} \frac{T_i I_{RMS,i}^2}{AF_i}} = \frac{\sum\limits_{i=1..N} T_i \frac{AF_i \cdot P_i^2}{U_{RMS,i}^2}}{\sum\limits_{i=1..N} \frac{T_i \frac{AF_i \cdot P_i^2}{U_{RMS,i}^2}}{AF_i}}, \quad (35)$$

this implies that, $U_{RMS,i}$ will act as a "weighting" coefficient. When it changes, the influence of a separate interval will change, although the voltage value is not related to the properties of the consumer. Therefore, in order for the assessment of energy efficiency of consumption to be independent of voltage fluctuations in the network, it is possible to take $U_{RMS,i} = const = U_{RMS}$, and, accordingly:

$$AF_T = \frac{\sum\limits_{i=1..N} T_i \frac{AF_i \cdot P_i^2}{U_{RMS}^2}}{\sum\limits_{i=1..N} \frac{T_i \frac{AF_i \cdot P_i^2}{U_{RMS}^2}}{AF_i}} = \frac{\sum\limits_{i=1..N} AF_i \cdot T_i \cdot P_i^2}{\sum\limits_{i=1..N} T_i \cdot P_i^2} \quad (36)$$

The minimal interval can be chosen to correspond to that corresponds to the network voltage period. In this case, the need to isolate periods of constant load is eliminated, and the approach becomes entirely generalizable.

V. Calculation Example

A consumer is powered by a network with an active resistance $r = 0{,}1$ Ohm. In this case, the effective voltage at the measurement point is constant and, regardless of the load, is $U_{RMS} = 230$ V. The consumer has two electrical appliances - an LED lighting lamp with a power of $P_{LED} = 10$ W and a power factor of $PF_{LED} = 0{,}5$, and a heater with a power of $P_{HT} = 1000$ W and a power factor of $PF_{HT} = 0{,}99$. It is necessary to calculate the total Active Loss Factor and power factor for a day, if the lighting lamp is turned on constantly, and the heater is turned on for 2 hours.

Solution. The entire time interval of 24 hours can be divided into 2 sections - $T_1 = 22$ hours when only LED lighting is working, and $T_2 = 2$ hours when the heater and LED lighting are working.

In the first section, based on (23), one can calculate the effective current value:

$$I_{RMS,1} = \frac{P_{LED}}{U_{RMS} PF_{LED}} = \frac{10}{230 \cdot 0{,}5} = 0{,}087 \text{ A}.$$

Accordingly, the Active Loss Factor in the first section:

$$AF_1 = \frac{1}{PF_{LED}^2} = \frac{1}{0{,}5^2} = 4.$$

In the second section, the total current equals the sum of individual branch currents from the lighting and the heater:

$$I_{RMS,2} == \frac{P_{LED}}{U_{RMS} PF_{LED}} + \frac{P_{HT}}{U_{RMS} PF_{HT}},$$

$$I_{RMS,2} = \frac{10}{230 \cdot 0{,}5} + \frac{1000}{230 \cdot 0{,}99} = 4{,}479 \text{ A}.$$

Accordingly, the Active Loss Factor and the power factor in the second section:

$$AF_2 = \frac{I_{RMS,2}^2 U_{RMS}^2}{P_2^2} = \frac{4{,}479^2 \cdot 230^2}{(1000+10)^2} = 1{,}040,$$

$$PF_2 = \frac{1}{\sqrt{AF_2}} = \frac{1}{\sqrt{1{,}040}} = 0{,}981.$$

According to (33), the calculation of the overall active loss and power factors can be evaluated using the following expressions:

$$AF_T = \frac{\sum\limits_{i=1..N} T_i I_{RMS,i}^2}{\sum\limits_{i=1..N} \frac{T_i I_{RMS,i}^2}{AF_i}},$$

substituting the obtained values:

$$AF_T = \frac{22 \cdot 0{,}087^2 + 2 \cdot 4{,}479^2}{\frac{22 \cdot 0{,}087^2}{4} + \frac{2 \cdot 4{,}479^2}{1{,}040}} = 1{,}043,$$

$$PF_T = \frac{1}{\sqrt{AF_T}} = \frac{1}{\sqrt{1{,}043}} = 0{,}979.$$

To validate the accuracy of the obtained energy efficiency assessment, the loss ratio should be calculated knowing the active resistance of the network.

Electrical energy losses can be calculated as:

$$W_{LS} = W_{LS,1} + W_{LS,2} = r \cdot T_1 \cdot I_{RMS,1}^2 + r \cdot T_2 \cdot I_{RMS,2}^2,$$

$$W_{LS} = 0,1 \cdot 22 \cdot 0,087^2 + 0,1 \cdot 2 \cdot 4,479^2 = 4,028 \text{ Wh}$$

Minimum electrical energy losses would occur if both loads had a power factor of 1. Then:

$$I_{RMS,MIN,1} = \frac{P_{LED}}{U_{RMS} PF_{MAX}^2} = \frac{10}{230 \cdot 1^2} = 0,043 \text{ A},$$

$$I_{RMS,MIN,2} = \frac{10}{230 \cdot 1^2} + \frac{1000}{230 \cdot 1^2} = 4,391 \text{ A},$$

$$W_{LS,MIN} = W_{LS,MIN,1} + W_{LS,MIN,2} = r \cdot T_1 \cdot I_{RMS,MIN,1}^2 + r \cdot T_2 \cdot I_{RMS,MIN,2}^2$$

$$W_{LS,MIN} = 0,1 \cdot 22 \cdot 0,043^2 + 0,1 \cdot 2 \cdot 4,391^2 = 3,861 \text{ Wh},$$

$$\frac{W_{LS}}{W_{LS,MIN}} = \frac{4,028}{3,861} = 1,043 .$$

Thus, the integral coefficient corresponds to the ratio of losses according to the considered model.

For comparison, simplified approaches to assessing energy efficiency can be used. For example, if the power factor is averaged over time, the result will be completely different:

$$PF_T = \frac{PF_1 \cdot T_1 + PF_2 \cdot T_2}{T_1 + T_2} = \frac{0,5 \cdot 22 + 0,981 \cdot 2}{22 + 2} = 0,540$$

This clearly indicates that such a value does not reflect the real picture and properties of the load.

Another possible way is to calculate the Active Loss Factor for the entire 24-hour period. It can be shown that the root-mean-square current per day will be equal to:

$$I_{RMS,T} = \sqrt{\frac{I_{RMS,1}^2 \cdot T_1 + I_{RMS,2}^2 \cdot T_2}{T_1 + T_2}} = \sqrt{\frac{0,087^2 \cdot 22 + 4,479^2 \cdot 2}{22 + 2}} = 1,296$$

A, and the average power:

$$P_{AVG} = \frac{P_1 \cdot T_1 + P_2 \cdot T_2}{T_1 + T_2} = \frac{10 \cdot 22 + 1010 \cdot 2}{22 + 2} = 92,5 \text{ W}.$$

Based on the data obtained, the power factor will be equal to:

$$PF_T = \frac{P_{AVG}}{U_{RMS} I_{RMS,T}} = \frac{92,5}{230 \cdot 1,296} = 0,310 ,$$

which does not adequately represent the actual characteristics of the load. This discrepancy arises because non-stationarity also affects the value of PF_T. But, in our opinion, the requirement of complete stationarity of consumption is unrealistic and inconsistent with actual behavior of consumers. Therefore, such an estimate has no practical meaning, despite being mathematically valid.

CONCLUSION

(i) The paper offers a physically grounded interpretation of the power factor (PF), clarifying the operating conditions under which it attains its best value and explaining why practical measurements may deviate.

(ii) The Active Loss Factor (AF) is a more practical, loss-centric indicator of consumption efficiency: it directly reflects the copper-loss penalty and remains meaningful under nonsinusoidal and nonstationary operation.

(iii) The proposed time-aggregated methodology enables robust, comparable assessments for arbitrary loads using only standard metering data (RMS voltage, RMS current, active power), without specialized instrumentation.

***Abstract* – The article discusses the issues of constructing computer models of an electric drive with distributed mass and elasticity of the mechanical part using the example of armored face conveyors. Mathematical models were obtained. Various methods of description were used: frequency approximation, block diagrams, vector-matrix apparatus, graphs method. The results were compared, including areas of expedient application in solving typical problems of calculating dynamic processes of a conveyor in characteristic technological modes of its operation: soft start from an intensity setter and in current limiting mode, sudden braking from emergency chain jamming, and others. The wave processes of displacements, velocities and accelerations in a 200-mass elastic-viscous chain model coupled with a model of a cascade speed control system are shown in 3-D representation. An appropriate range of values of discrete elements along the length of the discretized chain is determined. New features in dynamic processes were discovered, new analytical dependencies were obtained.**

Keywords – electromechanical system; armored face conveyor; multi-mass drive system; speed control system; dynamic load.

I. Introduction

As industrial electric drives improve in the direction of increasing accuracy and speed and the development of synthesis algorithms, more and more attention has to be paid to clarifying the description of the mechanical part, at least to check the performance of synthesized controllers. The problem of taking into account the so-called unmodeled dynamics in the synthesis of automatic control systems has not yet been posed on a large scale or is being solved using robust controllers [1]–[5].

Methods for describing mechanical systems, developed in the theory of mechanical vibrations, are mainly focused on another task: determining the frequencies and shapes of vibrations, and, secondly, they require an inappropriately large amount of time from an electrical specialist to master them and use them professionally, taking into account the need for coupling models of the mechanical part with a model of the electrical part of the drive and features of the technological process. Similar remarks can be made in relation to the material in a small section of the theory of automatic control devoted to systems with distribution parameters [6]–[8]. The mathematical apparatus of this section turned out to be practically unclaimed by electric drives in their scientific articles, and there is, most likely, the only monograph on the electric drive of mechanisms with distributed mass and rigidity [9].

At the same time, the well-known method of discretizing an object with distributed mass and rigidity on the basis of physical concepts requires knowledge only of Newton's law and Hooke's law, and therefore is accessible to schoolchildren. Therefore, the question of the feasibility and effectiveness of using one or another method for describing distributed systems when solving specific electrical drive problems requires clarification [10], [11]. Let's consider it using examples of the dynamics of a conveyor chain, keeping in mind that modeling the rod itself is not the final goal when building a model of the mechanical part of these electric drives [12], [13].

II. Modeling the Mechanical Part of a Conveyor with an Elastic-Viscous Chain without a Sagging Loop

In the absence of a sag loop, the chain has sufficient tension to consider it as a rod, the ends of which are brought together into a ring and rigidly fixed to a concentrated sufficiently large mass corresponding to the inertia of the engine rotor. If the mass of the rotor were infinitely large, then such a scheme would correspond to the termination of a straight rod at both ends, however, such a simple solution, especially taking into account the presence of a control system, cannot be accepted for consideration as a complete model. In the theory of oscillations [14], [15] a number of simple standard design schemes are considered, but for them, mainly, the natural frequencies and mode shapes are obtained and, in addition, there is no solution to the partial differential dynamics equations for the considered conveyor scheme.

In publication [16], the oscillation frequencies are also determined for the conveyor, but there is no solution to the dynamics equations. The mentioned calculation formulas for oscillation frequencies are, naturally, very convenient to use to check the correct operation of the conveyor model when modifying its design scheme to the diagrams [17], [18]. This allows you to evaluate the efficiency of the model set in Matlab element by element - for example, separately for a conveyor chain or when specifying the moment of inertia of the rotor $J \to \infty$.

Only in a few (unfortunately) works are there solutions to the equations of rod dynamics that are available for direct use by an electrical engineer. Thus, in [19] a calculation formula is presented for determining the displacements $\eta(x, t)$ of points along the length x of a homogeneous massive elastic rod with single-end embedding during longitudinal vibrations without taking into account damping.

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

$$\eta(x,t)=\frac{2P}{lEF}\sum_{n=1}^{\infty}\frac{(-1)k^{n-1}\cos(\lambda_n t)\sin(k_n x)}{k_n^2}, \qquad (1)$$

where P – is the tensile force of the rod along the length of the conveyor chain, N;

l – is the conveyor chain length, m;

E – is the Young's modulus of rod material, N/m^2;

F – is the cross-sectional area of the rod, m^2;

n – is the number of members of the series;

λ_n – is the rod longitudinal vibration frequency;

k_n – is the wave number.

The solution, as can be seen, was obtained in the form of a sum of a series of harmonics, that is, it is approximate, the quality of the approximation of which depends on the value n used - the number of terms of the series.

A graphical representation of the solution $\eta(x, t)$ with the number of harmonics n=1250, performed by the authors of the article in the Maple package, is shown in Fig. 1.

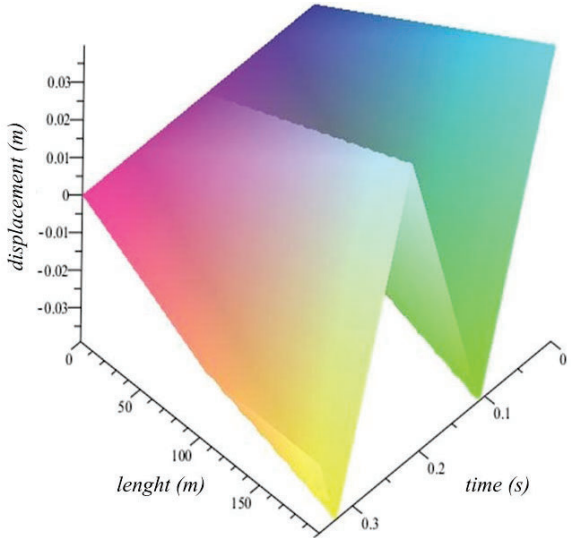

Fig. 1. Displacement, in meter, of conveyor chain points $\eta(x, t)$ along its length, in meter, and in time, sec

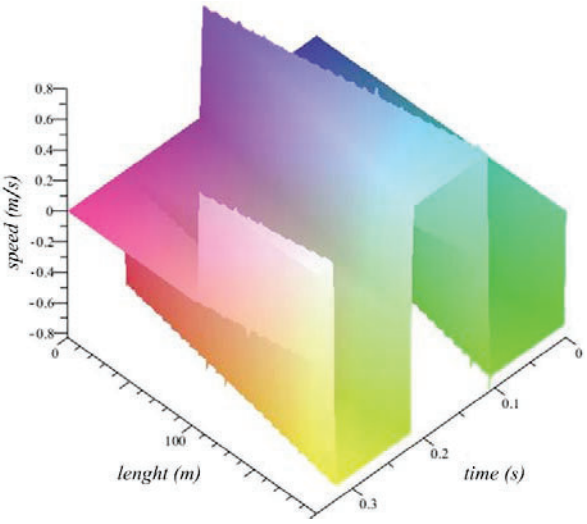

Fig. 2. Velocities of conveyor chain points $v(x, t)$ along its length and in time

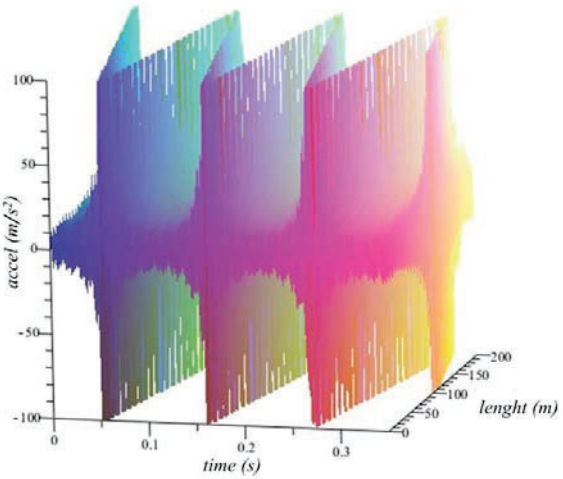

Fig. 3. Acceleration of conveyor chain points $a(x, t)$ along its length and in time

Formula (1) $\eta(x, t)$ in the same package was analytically differentiated (after correcting typos in the text of the textbook) to obtain graphs of velocities and accelerations. They are shown in Fig. 2, Fig. 3.

From Fig. 1 and Fig. 2 it is clear that the solutions correctly display the physical processes of the passage of a wave along the rod, but the shape of the acceleration graphs, and therefore forces, is no longer acceptable for consideration at a graphic resolution of 150x150, and at a resolution of 500x500 image processing on the screen of a good computer occurs with such a delay that it becomes almost impossible to turn it to the desired angle.

The possibility of applying formula (1) is exhausted here. It cannot be used to plot dynamic processes in another design scheme, for example, when embedding a rod on both sides. Even to calculate the considered scheme, but with damping in the rod, you need to obtain a different calculated dependence. Last presented Here same in [19] in form (2).

$$\eta(x,t)=e^{-ht}\sum(A_n\cos\lambda_n^* t+B_n\sin\lambda_n^* t)\sin\frac{(2n-1)}{2l}\pi x, \qquad (2)$$

$$\lambda_n^*=\sqrt{\lambda_n^2-h^2}, \qquad (3)$$

$$\eta(x,0)=\frac{Px}{EF}, \quad \eta(x,0)=0, \qquad (4)$$

$$A_n=\frac{P}{EF}\frac{\int_0^l xX_n(x)dx}{\int_0^l X_n^2(x)dx}, \qquad (5)$$

$$B_n=\frac{Ph}{EF\lambda_n^*}\frac{\int_0^l xX_n(x)dx}{\int_0^l X_n^2(x)dx}. \qquad (6)$$

However, it is no longer possible to carry out calculations without finding the values of the coefficients A_n and B_n under specific boundary conditions. In addition, it is not clear why the exponent e^{-ht}, corresponding to the damping of the process, turned out to be a multiplier beyond the sum of the harmonics and, thus, the free damping of movements at different frequencies becomes the same tempo for both low and high frequencies. That is, fast ones turn out to be worse damped. This is not physical and, moreover, it is not clear that in [15]

another calculation formula (7) is given for solving the same problem.

$$u = \sum_{r=1}^{\infty} X_r(x) e^{-n_r t} (A_r \sin p_r^* t + B_r \cos p_r^* t), \quad (7)$$

$$p_r^* = \sqrt{p_r^2 - n_r^2} = p_r \sqrt{1 - \left(\frac{k p_r}{2E}\right)^2}, \quad (8)$$

$$n_r = \frac{k p_r^2}{2E}. \quad (9)$$

In it, each frequency of damped oscillations has its own exponential and, moreover, it is noted that due to damping, the upper frequencies in the record of the series cease to exist and "... the corresponding terms of the general solution will represent movements of a non-oscillatory nature." This corresponds to general physical concepts about the nature of damping processes in structural materials, however, formulas for calculating coefficients A and B are not given.

To summarize this brief selective but representative analysis, it should be noted that in the considered basic sources, unfortunately, there are no completed calculation formulas and, moreover, their summary tables for determining the forces, accelerations, velocities and displacements of different sections of the elastic-viscous massive rod with different design schemes in terms of boundary conditions and the presence of connecting masses of different sizes at different points of the rod. This does not allow the electrical engineer to take advantage of the indicated results of applying the methods of the theory of vibrations of mechanical systems.

Without analyzing a number of other methods of the theory of mechanical vibrations, including the finite element method (which gives the desired results, but requires significant labor to master and time to use), as well as difference methods of mathematical physics, let us move on to considering the method of direct discretization of a rod into elastically coupled masses. This method is extremely simple in its physical interpretation and mathematical apparatus, requiring the use of only Newton's law and Hooke's law when drawing up the differential equations of the model.

The direct sampling method was used to construct a model of the electric drive of a scraper conveyor and study the dynamic processes in it [20]–[22] in normal and emergency operating modes. The model was represented in the Matlab package by a structural diagram of a 200-mass elastic-viscous chain with a model of an electric drive, a fluid coupling, a model of rock formation fall, nonlinear friction, etc. This model was checked for the coincidence of natural frequencies with the calculated values according to [9], [14], [15], [19]. However, on such a fairly complete model, the calculation of processes takes quite a long time and it is difficult to evaluate the dynamic properties of its linear part when changing the values of parameters and, especially, the number of masses, since this requires changing the structural diagram itself.

For analyzing the dynamic properties of the linear part of the conveyor model, a much more convenient model is the one presented in the m-file of the Matlab package in a matrix description. The calculation and display of its results occurs several times faster, so it is possible to track and analyze a larger amount of information. Thus, it was found that the circular and open-loop design schemes are characterized by a circular distribution of the roots of the characteristic equation of the conveyor model, as shown in Fig. 4.

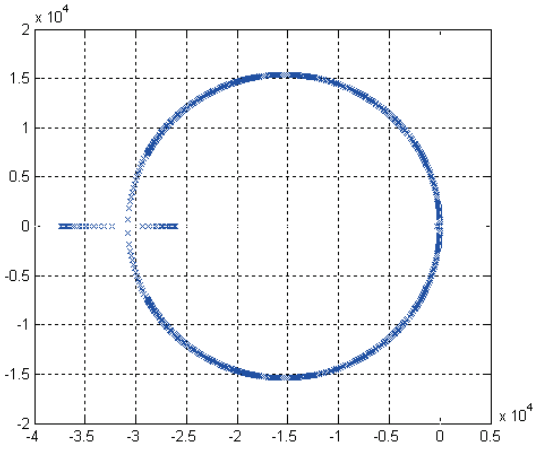

Fig . 4. Distribution of roots of the characteristic equation of the conveyor model

The roots are placed on a circle starting at the origin of the complex plane. First, with increasing frequency, the damping of each pair of roots increases, then the frequency begins to decrease and fast movements caused by remote left roots become non-oscillatory, as noted in [23]. During the variation of the chain parameters, it was found that the radius of this circle is inversely proportional to the coefficient of internal viscous friction β_{12} and directly proportional to the stiffness coefficient c_{12}, constant and equal to $R = c_{12}/\beta_{12}$.

It is advisable to emphasize that exactly this value of the radius of the circle for placing the roots can be obtained through a series of transformations of the solution to the partial differential equation [23]:

$$\frac{d^2u}{dt^2} = c^2 \frac{d^2u}{dx^2} + \frac{k}{\rho} \frac{d^3u}{dx^2 dt}. \quad (10)$$

Equation (10) describes the dynamics of an elastic-viscous rod using dependencies (7,8,9). Moreover, this solution is analytical; it was obtained by the Fourier method, and not by direct discretization of the rod. The roots, which are easy to obtain from the presented dependencies, coincide with the roots obtained for the model with discretized masses (n=50) for 10–20 lower frequencies, as can be seen from Fig. 5, and then begin to shift relative to each other, remaining, however, on a circle of radius $R=c_{12}/\beta_{12}$.

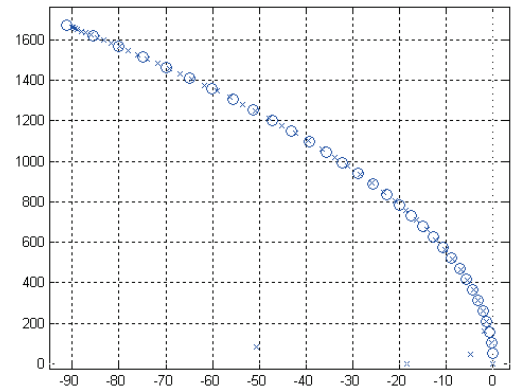

Fig . 5. Distribution of roots obtained for the model with discretized masses (n=50)

The same distribution of roots occurs for n=200, as can be seen from Fig. 6.

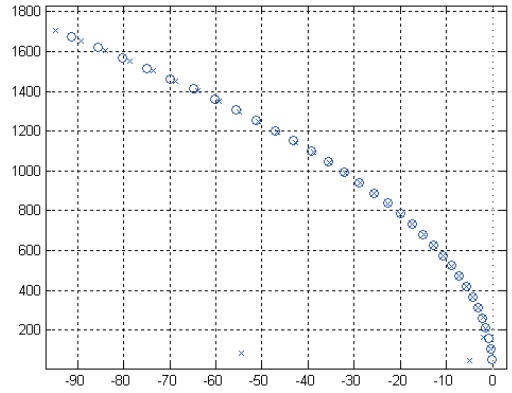

Fig . 6. Distribution of roots obtained for the model with discretized masses (n=200)

It is important to note that the roots in the dependencies [22] were obtained to describe the dynamics of a rod with a double-sided end seal, and the roots of the conveyor model were obtained on a model that included both a massive elastic-viscous tensioned chain and a drive using a cascade control system. These results make it possible to judge both the magnitude of the error caused by the discretization of masses and the extent of the influence of the drive control system on the wave processes of the conveyor chain.

Model calculations performed when varying the number of conveyor masses from 20÷30 to 200 for a two-drive conveyor with cascade control systems configured to a symmetrical optimum and an undamped or weakly damped chain model showed that at 60<n<120, several right-hand complex-type equations appear among the roots of the characteristic equation conjugate to the small real part. This suggests that such a system needs to be modeled with a mass number n>150. Then these roots return to the ordinate axis, otherwise erroneous conclusions can be drawn about the instability of the modeled object, and although for a two-drive conveyor it is not recommended for use, setting it to a symmetrical optimum due to increased oscillation caused by elastic coupling through the chain and possible fall into self-oscillatory mode when there is a difference tasks for speed, its frequency response has a less pronounced chain of resonant peaks, which interfere with the construction of simple controllers with a single-drive conveyor or when setting a two-drive conveyor to a betragsoptimum. Thus, a two-drive conveyor with drives configured to a symmetrical optimum, provided there is a current equalization subsystem, is a more favorable control object when solving problems of damping elastic vibrations in the system under consideration with distributed parameters. Therefore, we can conclude that the matrix model in the form of an m-file allows you to quickly obtain interesting and useful information about a system with a massive elastic-viscous traction body at the level of using simple engineering knowledge.

To check the correctness of the matrix model of the conveyor, compiled in the Matlab package, its model was developed in the form of a block diagram and its transfer functions were obtained using the graph method [24], [25] in the Maple package. Since the transfer functions were obtained in the symbolic transformation mode, the error in the final calculation of their coefficients is determined only by the number of reliable decimal places after the decimal point. In Matlab this number is 16, and in Maple it is specified by the user, and was chosen by the authors as 64. Such a strict approach was adopted after assessing the number of non-overlapping contours in the model. To determine their number, as a result of the analysis of the structural diagram and its generalization, the following formula (11) was obtained:

$$N_k = \frac{1}{k!}\prod_{i=0}^{k-1}(n-(k-1+i)), \tag{11}$$

where N_k – is the total number of k non-touching loops (two for k=2, three for k=3, etc.) in all combinations considered;

n – is the total number of loops of the structural diagram of the chain model of the rod;

Π – product sign.

The number of non-touching loops in the chain model is enormous. It is presented along the ordinate axis in Fig. 7 and for models of n=100 and n=200 masses lies, respectively, in the range of $10^{40}\div10^{80}$. Fortunately, the loops are of the same type, the transfer functions of one $W_1(p)$, two $W_2(p)$, three $W_3(p)$, and the number of $W_k(p)$ non-touching loops k are written simply:

$$W_1(p) = \frac{c_{12}+\beta_{12}p}{mp^2}, \tag{12}$$

$$W_2(p) = \left(\frac{c_{12}+\beta_{12}p}{mp^2}\right)^2, \tag{13}$$

$$W_3(p) = \left(\frac{c_{12}+\beta_{12}p}{mp^2}\right)^3, \tag{14}$$

$$W_k(p) = \left(\frac{c_{12}+\beta_{12}p}{mp^2}\right)^k, \tag{15}$$

where c_{12} – is the stiffness coefficient between the first and second scraper;

β_{12} – is the coefficient of internal viscous friction between the first and second scraper;

m – is the scraper weight;

k – is the number of masses.

In this case, the maximum value of k is equal to $k_{max}=n/2$, where n is the number of circuits of the chain model (it is even).

Taking into account the obtained dependencies, the transfer function of the entire model is written in the Maple package in general form as:

$$W_1(p) = \frac{R(p)}{Q(p)}, \tag{16}$$

$$R(p) = \frac{1}{mp}(W_1(p))^{\frac{n}{2}}(mp^2)^{\frac{n}{2}}, \tag{17}$$

$$Q(p) = \Delta(mp^2)^{\frac{n}{2}}, \tag{18}$$

$$\Delta = 1 + N_1W_1(p) + N_2W_2(p) + N_3W_3(p) + \ldots$$

$$N_kW_k(p) + \ldots + N_{\frac{n}{2}}W_{\frac{n}{2}}(p). \tag{19}$$

This allows, with an accuracy of up to 64 or more decimal places of coefficients for known numerical values of the model parameters, without solving equations to find the roots of the characteristic equation of the resulting transfer function, to construct frequency characteristics in the Maple package and compare their resonant frequencies with the resonances of the matrix model in Matlab. The comparison showed the coincidence of the resonant frequencies of the models of the considered electromechanical conveyor system with distributed mass, elasticity and viscosity of the chain, obtained in different packages using different algorithms, which indicates the correctness of modeling an electric drive with a complex mechanical subsystem.

We will simulate dynamic processes using a computer model developed by the authors [26], [27] of a one- and two-drive armored face conveyor CP72 with an adjustable asynchronous electric drive with a vector control system, which is represented by a standard double-loop speed control system under the assumption of fully functioning flow loops (Fig. 7). This model makes it possible to study the start-up in current-limiting mode and the soft start of a conveyor, its operation at a certain transportation speed, as well as chain jamming for various reasons.

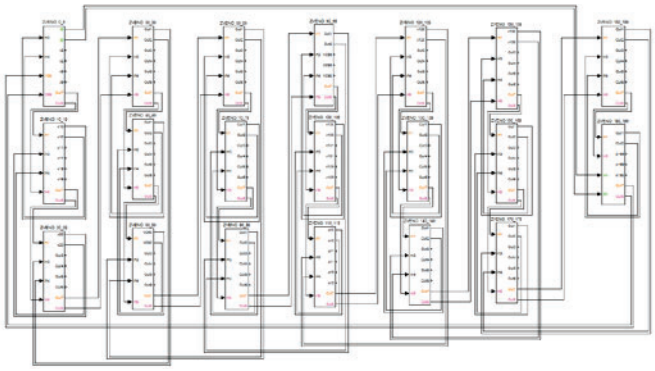

Fig. 7. Block diagram of the 200-mass model of armored face conveyor for Matlab

The mechanical part of the conveyor in the model is represented by a system with lumped parameters and consists of 200 elementary blocs interconnected. Each elementary bloc of the working branch is characterized by a total mass m_i=118 kg (chain, scraper and load), elasticity k=2·108 n/m and chain viscosity β=3000 n·s/m. Each mass is affected by the sliding friction forces of coal on steel with a friction coefficient Ψ=0.45 [15], with an inclined route - projections of the gravitational force, as well as elastic-viscous forces from neighboring links. The movement of the working body is described by a system of differential and algebraic equations compiled on the basis of Newton's second law and Hooke's law.

$$\begin{cases} m_1 \dfrac{dV_1}{dt} = F_{ef12} - F_{ef01} + F_{vf12} - F_{vf01} + F_{ff1}, \dfrac{dX_1}{dt} = V_1, \\ m_2 \dfrac{dV_2}{dt} = F_{ef23} - F_{ef12} + F_{vf23} - F_{vf12} + F_{ff2}, \dfrac{dX_2}{dt} = V_2, \\ m_n \dfrac{dV_n}{dt} = -F_{ef(n-1)n} - F_{vf(n-1)n} + F_{ffn}, \dfrac{dX_n}{dt} = V_n, \end{cases} \quad (20)$$

where m_1, m_2, m_n – is the scrapers weight, kg;
X_1, X_2, X_n – is the chain scraper coordinates, m;
V_1, V_2, V_n – is the speed of scrapers, m/s;
F_{ff1}, F_{ff2}, F_{ffn} – is the friction forces, N;
F_{ef01}, F_{ef12}, F_{ef23}, $F_{ef(n-1)n}$ – is the elastic forces, N;
F_{vf12}, F_{vf23}, $F_{vf(n-1)n}$ – forces of internal viscous friction, N.

In Fig. 8 shows three-dimensional space-time diagrams of dynamic processes of speeds V(x, t) in the conveyor chain.

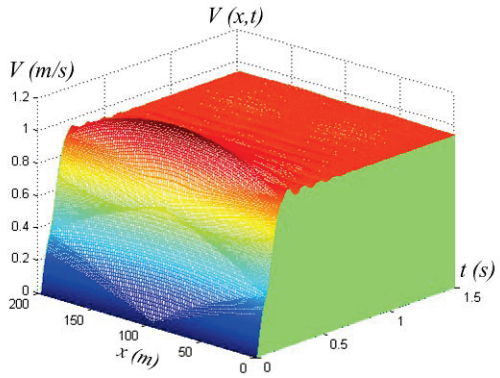

Fig. 8. Three dimensional representation of dynamic processes velocities of chain elements

Dynamic processes calculated in the model of an unloaded armored face conveyor when starting from one asynchronous adjustable electric drive located at the head of the conveyor. The speed controller in the electric drive model is proportional [28]. The chain pretension value in the model is equal to F_{pv}=44 kN, there is no sag, the modeled chain is elastic in tension and "compression" relative to the pretension level. From Figure 8 it can be seen that the deformation wave propagates from the point where the force is applied and is reflected from the free end of the conveyor. The presence of damping in the "drive" ensures damping of oscillations during 4-5 passes of the wave along the conveyor. The frequency of these oscillations is 8.3 Hz.

Figure 9 shows three-dimensional space-time diagrams of dynamic processes of forces F(x, t) in the chain.

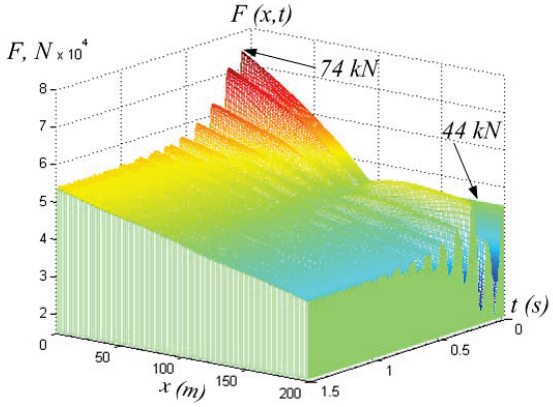

Fig. 9. Three-dimensional representation of dynamic processes of forces in a chain

From the consideration of the processes, we can conclude that starting a single-drive conveyor in current limiting mode (during the acceleration time t=0.2 s) with a maximum torque leads to the emergence of natural oscillations of forces in the chain with a frequency of 8.3 Hz, the amplitude of which is maximum near the drive station 74 kN taking into account F_{pv} and decreases with distance from it [29]. After the conveyor accelerates, the resulting oscillations die out, the induction motor transmits traction force to the working and idle branches, the maximum load in the chain at the run-up point near the drive station is 10 kN without taking into account F_{pv}.

III. CONCLUSIONS

The article presents a comparative analysis of engineering techniques for modeling mechanical systems with distributed masses and elasticities, using the electric drive of a chain conveyor as an example. The research demonstrates the effectiveness of different modeling approaches for solving typical problems related to conveyor operation, such as soft starts, current limiting and sudden braking.

A finding is the discovery of the circular distribution of the characteristic equation's roots for the conveyor model with a PI speed controller in the complex plane. This distribution is inversely proportional to the coefficient of internal viscous friction and directly proportional to the stiffness coefficient, with a constant radius $R=c_{12}/\beta_{12}$. It was also shown that roots from an analytical solution obtained via the Fourier method coincide with those from the direct discretization model for the first 10-20 lower frequencies.

The study also revealed a previously unmodeled phenomenon: the potential for soft self-excitation and instability in the system under certain conditions, which necessitates modeling with a high number of masses, specifically $n>150$. This is particularly relevant for a two-drive conveyor configured to a symmetrical optimum, which, despite its tendency towards oscillations, offers a more favorable control object for damping elastic vibrations when a current equalization subsystem is present.

Furthermore, a novel formula was derived to calculate the number of non-touching loops in the structural diagram of the model for obtaining its transfer function using the graphs method (topological method). The correctness of the developed matrix and block diagram models was confirmed by the coincidence of resonant frequencies obtained in different software packages (Matlab and Maple) using distinct algorithms. This comprehensive set of results enables rapid and accurate modeling of electromechanical systems with complex mechanical subsystems, providing a robust framework for further analysis and controller synthesis.

***Abstract*—The article presents the construction of a functional model of a biomedical protection system and conducting experimental studies of absorbing materials exposed to electromagnetic radiation. It is shown that the resistive absorbing material based on polystyrene foam with the addition of graphite has the feature that allows implementing the calculated laws of change in complex dielectric permittivity.**

Keywords—absorbent material, biomedical protection system, polystyrene foam, functional model.

I. Introduction

In recent decades, there has been a rapid development of communications, radar, wireless technologies and medical electronics. However, in parallel with the growth in the intensity of the use of electromagnetic radiation (EMR), the impact of these factors on humans and the environment is also increasing. Studies show [1–3] that one of the reasons for the deterioration of human health in conditions of increased EMR levels is a change in the characteristics of the body's own energy fields. Such changes can manifest themselves in the disruption of individual organs, changes in biochemical processes and even at the molecular level [4–5].

Under short-term conditions of exposure, the body is able to partially or completely compensate for the negative impact of the external field due to its own protective mechanisms [6]. However, with prolonged exposure to an area of increased electromagnetic background, changes accumulate, which can lead to stable pathological processes of varying severity. In this regard, there is an urgent need to develop effective biomedical protection systems capable of reducing the negative impact of electromagnetic radiation. One of the promising areas is the use of special absorbing materials that provide shielding and minimize reflections in a wide frequency range [7-8]. Modern polymer-based materials with the addition of conductive fillers (for example, graphite) allow varying their electrodynamic properties and selecting the optimal parameters for protecting humans and sensitive medical equipment.

Thus, an urgent task is to develop a functional model of a biomedical EMI protection system, select and study materials with optimal characteristics, and experimentally test their effectiveness.

II. Functional Model Of The Biomedical Protection System

The aim of the work is to develop and experimentally study a functional model of a biomedical system of protection against electromagnetic radiation, as well as to study the properties of polymeric materials with the addition of graphite to create effective absorbing structures that reduce the level of reflection and increase the shielding factor in a wide frequency range.

The synthesis of an optimal biomedical protection system (OBPS) can be performed on the basis of a generalized functional-statistical criterion [9]. In this case, in general, for synthesis it is necessary to know the laws of probability distribution of X, G, Z, U, V, Y, F random vectors. Knowledge of the characteristics of these vectors will make it possible to determine the necessary generalized indicators for assessing the effectiveness of protection [10-16]. For X, G vectors, we can confine ourselves to determining the intensity of microwave radiation (the values of the electric E and magnetic H components) for various radiation sources.

When solving the problem of system synthesis, based on the permissible values of Y and F vectors, it is necessary to synthesize devices for biological protection against electromagnetic radiation (EMR) and select control laws for U and V. Fig. 1 shows a functional model of a biomedical protection system with EMR sources that are affected by a certain vector of external and internal disturbances $Z(z_1, z_2,\ldots,z_j)$, which is random in nature. The action of EMR sources also determines the randomness of $X(x_1, x_2,\ldots x_n)$ vector and the vector of sources $G(g_1,g_2,\ldots,g_n)$.

The vector of output coordinates of the EMR source can determine the spatial and temporal positions of the j-th object, and also carry information about the states of EMR sources when the vector of control signals $U(u_1, u_2,\ldots u_t)$ acts on the microwave radiation source and on the protection system $V(v_1,v_2,\ldots,v_t)$, generated by the monitoring and control system (MCS). By performing

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

measurements of X, G vectors, characterizing the states of the EMR before and after the environment, the MCS generates $U(U_1, U_2,\ldots,U_n)$ and $V(V_1,V_2,\ldots,V_m)$ control vectors. The protection system forms $Y(y_1, y_2,\ldots,y_k)$ vector. The damage to the biological environment is characterized by $F(f_1, f_2,\ldots,f_i)$ vector. The functional diagram shows (Fig. 1) the main connections between the elements of the BMPS control and management system, which make it possible to construct mathematical models for individual blocks of the system.

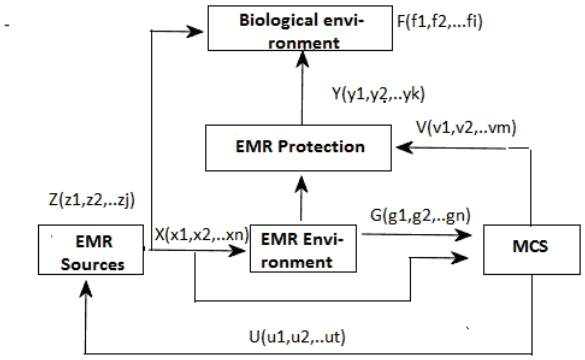

Fig.1. Functional block diagram of the Biomedical Protection System (BMPS).

EMR sources S under disturbances Z generate an incident field $X=\{E, H\}$. The Monitoring & Control System (MCS) measures X and source state G, estimates biological impact F, and issues controls U (to sources, if accessible) and V (to the protection system P). The protection system transforms the incident field into a mitigated field Y at the protected biological object B.

III. Manufacturing Absorbing Material

The protective properties of the material based on polystyrene foam with the addition of crushed graphite particles of different particle sizes in the matching layer were studied. Depending on the time the granules are kept in hot water, it is possible to obtain polystyrene foam of varying density, which is directly proportional to the dielectric constant and can take a value from 1 to 2.5.

Due to the fact that the particle diameter in polystyrene foam and the wavelength in the millimeter range become quite close, there is a danger of increased reflection. To prevent such phenomena, the sizes of polystyrene foam granules were chosen to be equal to 2–5 mm. The prepared aquadag was applied in an even layer onto flat polystyrene foam plates measuring 75–45 cm, and exactly the same amount of aquadag by weight was applied to each plate. After drying, the plates were examined on an experimental installation that allows determining the characteristics of the material in the frequency range of 10–75 GHz. The best characteristics for this frequency range were demonstrated by aquadag with a graphite particle size of 30–70 μm, used in the manufacture of the absorbing material. After the first foaming, polystyrene foam granules are covered with a uniform film of aquadag with a certain concentration. After this, the granules are dried. The next stage of manufacturing the absorbent material is its formation. The granules, coated with aquadag, are loaded into the press form, and its filling by volume should be 100%. For free penetration of hot water into the mold and for gas to escape from it, it is necessary to make the walls perforated.

IV. Installation For Studying Absorption Materials

To study the amplitude-angular characteristics of the scattered field and determine the parameters of the absorbing material in free space, it is necessary to find out the optimal relationships between the electrodynamics, geometric and frequency characteristics of the experimental installation, required to obtain reliable measurement results. The distance in the ratio: “transmitting system – test sample and receiver” must correspond to the conditions under which the waves in the area of the material under study can be considered as plane. In this experiment, it is necessary to ensure the removal of the dependence of the scattered field pattern on the angle of incidence of the electromagnetic wave, and also to ensure minimal coupling of the antennas through parasitic re-radiations and their mutual multiple coupling directly through the sample under study.

To ensure reliable experimental results, wave reception interference due to extraneous radiation must be small, and the sensitivity of the receiver must be high.

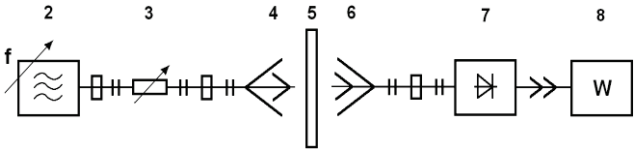

Fig. 2. Functional diagram of the experimental installation: 2 – microwave generator, 3 – attenuator, 4 – transmitting antenna, 5 – material under study, 6 – receiving antenna, 7 – receiving converter, 8 – indicator unit.

Changing the polarization of an electromagnetic wave can be accomplished by using a radiator with circular polarization or with linear polarization with two orthogonal polarizations. Obtaining greater accuracy with a relatively simple design is ensured in the second case.

The dependence of the directional pattern of the scattered field on the angle of incidence of the electromagnetic wave can be determined by moving the receiver around the sample under study while keeping the latter’s position unchanged. The proposed measuring installation largely satisfies the above requirements. In the room, to eliminate parasitic re-radiation between the antennas, an anechoic chamber was simulated using absorbing materials with a signal reflection level of 50 dB. The use of horn antennas with a sufficiently low level of side lobes and good matching with the transmitting path ensured minimal multiple coupling of the antennas. The amount of reflection was eliminated by using matching transformers at the antenna input. In this case, the error caused by the lens properties of the material in the studied area of measuring its parameters did not exceed 2%. The reflection coefficient is determined by comparing the signals reflected by the sample and the reference, measured under conditions where the attenuation factors are the same. A polished copper sheet of the same dimensions as the sample was used as a reference reflector. Since the materials under study absorb much more power than they reflect, it is

possible to measure the shielding factor using the substitution method without taking reflection into account. The module of the sample shielding coefficient is determined by comparing the signals received at the receiving antenna in the absence and in the presence of the sample being measured.

V. Experimental Studies Of Heterogeneous Materials

The material was manufactured in two types, differing in the principle of matching with free space, the dielectric constant of the base, the law of distribution of graphite in the material and the geometry of the front surface. The first type is a block with a flat front surface. It consists of a non-uniform lossless dielectric. In the frequency range of 10 GHz to 75 GHz and angles of incidence of the electromagnetic wave within the range of 0–70°, the dielectric constant varied from 1 to 2.0. The matching layer was made of five separate polystyrene foam plates with different dielectric constants, increasing from the first layer to the last one. The inhomogeneous lossy dielectric was made of five layers of polystyrene foam with ε = 2.0. Aquadag of varying concentrations was added to each layer as an absorbent material. The layers obtained in this way were connected in a certain sequence into a monolithic block and, together with the matching layer, formed the absorbing material of the first type. The second type of material has the same structure as the material of the first type, but without a matching layer. For this type of material, the dielectric constant of the base of the layers is close to unity. Figures 3-5 show the dependence of the reflection coefficient (Kot) in dB of an electromagnetic wave (EMW) on the first type of absorbing material with and without a matching layer as a function of the angle of incidence for various frequencies.

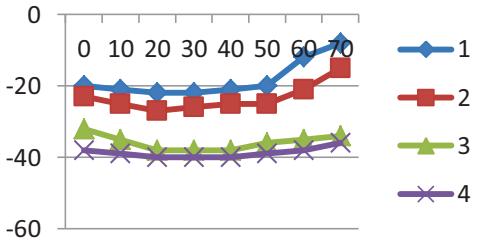

Fig.3. Dependence of Kot on the angle of incidence of the electromagnetic wave on the material at a frequency of 10 GHz .

The horizontal axis in Figs. 3–8 corresponds to the angle of incidence of the electromagnetic wave (in degrees), and the vertical axis corresponds to the reflection coefficient Kot expressed in decibels (dB). The curves numbered (1–4) represent measurements at different incident polarizations or different types of sample structures (with/without matching layer, or with flat/relief front surface).

Figures 6-8 present the results of studying the characteristics of the absorbing material with a shaped front surface. For a material with a relief front surface, the reflection coefficient depends significantly on the angle of incidence of the EMR and the plane of its polarization at a frequency of 75 GHz. With increasing electromagnetic wavelength, the absorption properties of the material deteriorate significantly.

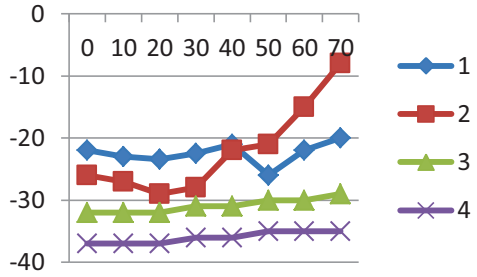

Fig.4. Dependence of Kot on the angle of incidence of the electromagnetic wave on the material at a frequency of 38 GHz.

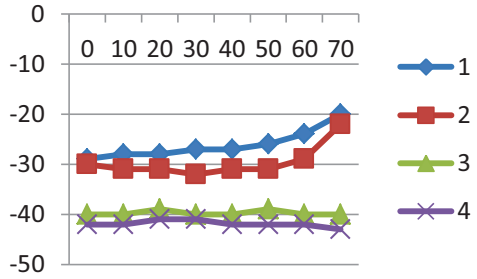

Fig.5. Dependence of Kot on the angle of incidence of the electromagnetic wave on the material at a frequency of 75 GHz.

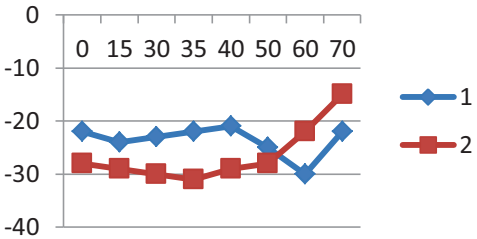

Fig.6. Dependence of Kot on the angle of incidence of the electromagnetic wave on the material at a frequency of 10 GHz.

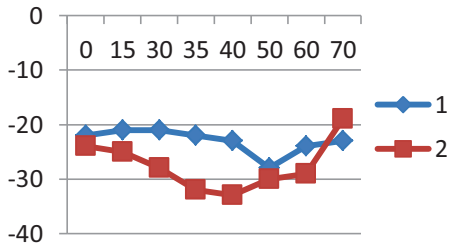

Fig.7. Dependence of Kot on the angle of incidence of the electromagnetic wave on the material at a frequency of 38 GHz.

Figures 3–5 show the dependence of the reflection coefficient Kot (dB) on the incidence angle (°) for absorbing materials with and without a matching layer at frequencies of 10 GHz, 38 GHz, and 75 GHz, respectively. Curves (1–4) correspond to different polarizations of the incident field. All dependencies were obtained experimentally on the measuring installation described in Section 3. Figures 6–8 present experimental dependencies of Kot (dB) versus incidence angle (°) for absorbing materials with a shaped front surface at the same frequencies. Curves (1–4) correspond to different orientations of polarization and measurement conditions.

These results were obtained by the authors and are not reproduced from external sources.

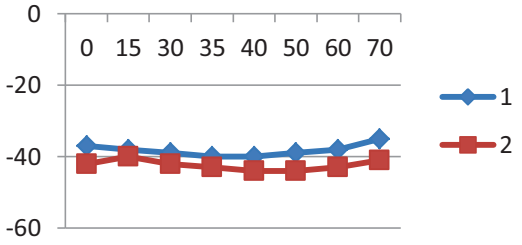

Fig.8. Dependence of Kot on the angle of incidence of the electromagnetic wave on the material at a frequency of 75 GHz .

This correction ensures that each graph is fully self-explanatory and its experimental origin is clear. Analyzing the graphs, we can conclude that the absorbing material without a matching layer has a higher reflection coefficient than with a matching layer. In addition, it is clear that the reflection coefficient of the material with the matching layer is almost independent of the angle of incidence. For the frequency range under study, the reflection coefficient exceeds – 30 dB and reaches -40 dB at a frequency of 75 GHz.

VI. Conclusions

An experimental study of absorbing materials exposed to electromagnetic radiation was carried out. In particular, an absorbing material without a matching layer with the addition of different concentrations of aquadag to each layer has a reflection coefficient greater than an absorbing material with a matching layer. The absorption properties of the material are practically independent of the angle of incidence of the electromagnetic wave. It has been experimentally proven that it is possible to create a material with the best reflection and absorption coefficients in a wide range of angles of incidence of an electromagnetic wave in the lower part of the frequency range. The use of cone-shaped reflective elements in the material leads to a significant increase in the absorption coefficient. It has been experimentally established that the EMR shielding material based on polystyrene foam with the addition of graphite has high shielding properties without the use of complex manufacturing technology. Aquadag with a graphite particle size of 30-70 microns has the best characteristics in the studied frequency range. There is also a laboratory base [17, 18, 19] and experience in creating telemedicine services [20-22], which can be useful for developing systems to protect medical personnel.

***Abstract*—This paper presents an analysis of mathematical and numerical models describing multifrequency piezoresonant oscillatory systems. Multifrequency excitation is a fundamental physical property of quartz resonators, arising from anisotropic elastic coupling. However, in the context of highly stable self-oscillatory systems used as reference frequency sources, this property is generally undesirable and often mitigated through design and manufacturing constraints. A critical review of existing mathematical models reveals that none can comprehensively describe the dynamics of piezoresonant systems subjected to vibrational destabilizing influences. To address this limitation, a new modeling approach is proposed, incorporating nonlinearities, environmental disturbances, and discrete boundary constraints. The model is validated through simulations in COMSOL Multiphysics and SolidWorks, using a piezoceramic disk mounted on four supports. Simulation results confirm the presence of multiple closely spaced resonant modes and demonstrate the sensitivity of system dynamics to mechanical stress and excitation conditions.**

Keywords—piezoresonant system, electronic, piezoelectric device, oscillations, multifrequency, model

I. INTRODUCTION

Quartz resonators are used in reference frequency generators, frequency-controlled oscillators, selective devices: filters, frequency discriminators, etc.

Quartz resonators are devices that utilize the piezoelectric effect to create electrical oscillations of a specific frequency. When the frequency of the applied voltage coincides with the natural frequency of the mechanical frequencies of the quartz vibrator, a resonance phenomenon occurs in the device, resulting in a sharp increase in conductivity [1].

Any piezoelectric resonant vibration system (RVS) can be considered as a multifrequency system, since it is the physical essence of the quartz crystal resonator (QSR). The anisotropy of the crystal element basically leads to various types of elastic coupling of stresses and strains and causes the appearance of lateral resonances in all piezoelectric resonant devices (PRD). Usually, multifrequency is an undesirable property of RVS and is combated by various design and technological methods. However, a constant increase in requirements for their metrological characteristics under the influence of not one destabilizing factor, but a complex (temperature, vibration, radiation, electromagnetic field, etc.), these methods are ineffective in solving the main problem of RVS - invariance to destabilizing factors [1].

The investigation of self-oscillatory systems becomes significantly more complex as the number of excitation frequencies increases. In [2], a generalization of the averaging techniques applied in the analysis of these systems is presented, addressing a differential equation system that includes a small parameter:

$$\frac{dp}{dt} = \varepsilon X(p,q)$$
$$\frac{dq}{dt} = \omega(p) + \varepsilon Y(p,q) \quad (1)$$

where $p = (p_1,...,p_m)$ is *an m-dimensional* vector of slow movements, $q = (q_1,...,q_n)$ is *an n-dimensional* vector of fast movements, $\omega(p) = (\omega_1(p), ..., \omega_n(p))$, and the vector functions *X*(*p*, *q)* and *Y*(*p*, *q)* can be represented as terms:

$$X(p, q) = \sum_{|k|\geq 0} X_k(p) e^{i(k, q)},$$
$$Y(p, q) = \sum_{|k|\geq 0} Y_k(p) e^{i(k, q)} \quad (2)$$

where $k = (k_1, ..., k_n)$ is a vector with integer positive and negative components, the norm of which is calculated by the formula: $|k| = \sum_{i=1}^{n} |k_i|$.

The solution of differential equations (1) relies on the assumption that the right-hand sides of these equations possess uniform mean values. Reference [2] demonstrates that the absence of uniform mean values results in discrepancies between the solutions of a system of differential equations of type (1) and the associated space-averaged system of variables (*q*).

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

$$\frac{dp}{dt} = \varepsilon \overline{X}(\overline{p}), \tag{3}$$

where.

$$\overline{X}(\overline{p}) = \frac{1}{(2\pi)^n} \int_0^{2\pi} \dots \int_0^{2\pi} X(\overline{p}, q) dq_1 \dots dq_n, \tag{4}$$

obtained at the same initial values, differ by a finite amount, at $t \sim \frac{1}{\varepsilon}$. This results in an equivalent system:

$$\frac{dx}{dt} = \varepsilon X(x + p_0,\ y + \omega_0 t + q_0),$$

$$\frac{dy}{dt} = \omega(x + p_0) - \omega_0 + \varepsilon Y(x + p_0,\ y + \omega_0 t) + q_0), \tag{5}$$

where $\omega_0 = \omega(p)$.

Thus, according to [3, 6], if the natural frequencies of the circuits are not in the ratio of prime integers and the attenuation of the circuits is sufficiently small, the reduced differential equations are represented by a system of the form (for single-circuit oscillators) [4]:

$$\begin{aligned} X_1 &= F_1(X_1, ..., X_n); \\ X_2 &= F_2(X_1, ..., X_n) \\ X_n &= F_n(X_1, ..., X_n) \end{aligned} \tag{6}$$

Where

$$F_i = [S_i(X_1, ..., X_n) R_i k_{33} - 1] X_i, \tag{7}$$

Where X *is the* relative dimensionless amplitude of oscillations; S_i is the average steepness for the fundamental frequency; R_i is the resonant impedance of the circuit; k_{33} is the feedback coefficient.

The steady-state equations, in which the amplitudes of oscillations are constant, are obtained from (6), (7) if we assume [7] $X_1 = X_2 = ... = X_n = 0$:

$$F_i = 0,\ i = 1, 2, ..., n,$$

from which the stationary values of the oscillation amplitudes X *are* determined$_{i0}$.

II. Main Part

A quartz crystal is an anisotropic body, and its physical properties vary in different directions. To describe the physical properties of quartz, as well as in engineering, the crystallographic coordinate system is mainly used, in the direction of which it has certain (characteristic for each axis) properties [8]. The crystallographic class (symmetry group 32), to which quartz also belongs, is characterized by the 3rd order symmetry axis (*Z)* and three pairs of 2nd order polar axes (*X* and *Y*) [9].

Here, *Z* is the "optical" axis, which coincides with the longitudinal axis of the crystal. In this direction, the piezoelectric effect does not appear, the electrical conductivity is higher than in the perpendicular direction, and there is no double refraction of the light beam. *The X-axis* is the "electric" axis, directed parallel to one of the prism faces; there are three *X-axes* in a quartz crystal. In the direction of *the X-axis*, mechanical forces cause intense electric charges to appear. *The Y* axis is the "mechanical" axis, directed perpendicular to *the m* faces; there are also three *Y* axes in a quartz crystal.

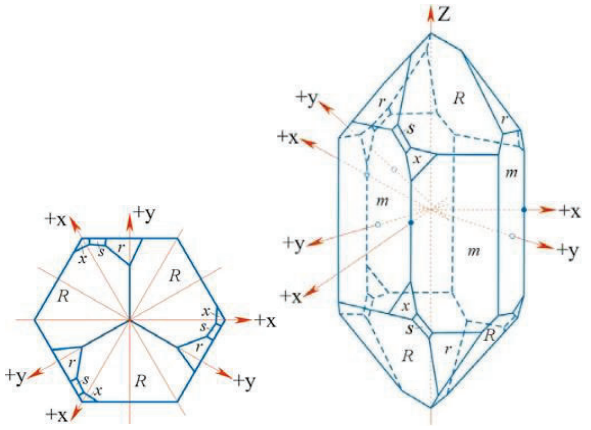

Fig. 1. Idealized enantiomorphic shape of α-quartz crystals and arrangement of crystallographic axes: *R* - basic positive rhombohedron; *r* - negative rhombohedron; *s* - trigonal bipyramid; *x* - trigonal trapezoid [9]

To manufacture quartz resonators, piezoelectric elements can be cut from a quartz crystal at different angles relative to the crystallographic axes in the form of plates of various shapes, bars, beams, etc. This orientation of the piezoelectric element is called a slice. There is a generalized conventional classification of quartz resonator cuts, which can be represented in the form of Fig. 1.

The symbol for the initial orientation of the piezoelectric element consists of two letters (*X*, *Y*, or *Z*): the first indicates which axis is parallel to the thickness of the piezoelectric element, and the second indicates which axis is parallel to its length. By rotating the piezoelectric element around its edges at different angles, a wide variety of orientations can be obtained - the so-called "oblique" sections.

The orientation designation of a piezoelectric element with edges forming angles with the crystallographic axes consists of the designation of the primary orientation, to which is added one, two, or three letters (*l*, *b*, *s*) indicating which directions (along the length, thickness, or width) of the piezoelectric element edges are used as axes of the first and subsequent rotations from the position of the primary orientation.

The angles of the first, second, and third rotations of the piezoelectric element around these axes are denoted by the letters α, β, and γ, respectively, which are placed through the oblique lines. The numbers that appear in place of these letters indicate the magnitude of the rotation angles. The angle of rotation is considered positive if the rotation is counterclockwise.

The orientation designation of a piezoelectric element with edges forming angles with the crystallographic axes consists of the designation of the primary orientation, to which is added one, two, or three letters (*l*, *b*, *s*) indicating which directions (along the length, thickness, or width) of the piezoelectric element edges are used as axes of the first and

subsequent rotations from the position of the primary orientation.

The angles of the first, second, and third rotations of the piezoelectric element around these axes are denoted by the letters α, β, and γ, respectively, which are placed through the oblique lines. The numbers that appear in place of these letters indicate the magnitude of the rotation angles. The angle of rotation is considered positive if the rotation is counterclockwise.

In [10] considered a model of a system for studying multi-frequency oscillations, which is described by a system of equations:

$$x + W_1(p)W_2(p)y - W_2(p)z - 0; \qquad (8)$$
$$y = F(x).$$

If the signals at the input and output of a nonlinear element (NLE):

$$x = x_0 + Ae^{j\omega_1 t} + Be^{j\omega_2 t}e^{j\alpha};$$
$$y = y_0 + AW(\omega_1/\omega_2)e^{j\omega_1 t} + BW(\omega_2/\omega_1)e^{j\omega_2 t}e^{j\alpha},$$

Where $W(\omega_1/\omega_2)$ is the transfer function excluding frequency ω_1 under the influence of the signal at frequencies ω_1 and ω_2; $W(\omega_2/\omega_1)$ is the transfer function excluding frequency ω_2 under the influence of the signal at frequencies ω_2 and ω_1 *; A, B are the* amplitudes of oscillations.

In addition to the above advantages of piezoresonant devices based on quartz resonators, they have a number of disadvantages and limitations, among which the most typical are sensitivity to external destabilizing factors such as temperature and mechanical stress. Under the influence of external mechanical influences, deformations occur on the piezoelectric element, which lead to changes in its geometric dimensions and density and, as a result, to changes in its natural resonance frequency. It is necessary to determine the distribution of mechanical stresses in the piezoelectric crystal with a high degree of accuracy [8, 10], taking into account the type of cut and orientation of the piezoelectric plate in space.

III. PRACTICAL IMPLEMENTATION

One of the structural and technological methods to increase the vibration resistance of piezoresonant devices is to improve the design of quartz holders [6, 7] and their usage [10]. First of all, the frequency properties of the quartz holder structures are studied, which must satisfy the provision that the frequency of natural oscillations of the structure should be outside the range of the vibration frequency acting on the quartz resonator. The methodology of such studies is as follows. The spectrum of resonant frequencies of the structure and the dependence of the spectrum on the variable parameters are determined, taking into account both random (due to tolerances on the structural elements) and systematic (due to differences in the size of the piezoelectric elements) frequency shifts. This dependence, as well as the spectrum, can be determined theoretically. The results of calculations based on the formulas, as well as the experimental determination of the quality factor of the mounting system, allow us to select the necessary parameters of already known structures (for this purpose, the nomogram method is used) [11]. Develop new vibration-resistant systems for mounting quartz elements by reducing the size of the quartz holder, using mounting elements with a sufficiently large cross-sectional area, high elastic modulus, etc [12].

Various design and technological parameters of the quartz resonator, such as the type of cut, the configuration of the holder, the number of piezoelectric element attachment points and their relative position, etc., have a significant impact on short-term frequency changes. At Fig. 2 we can see the advantages of attaching piezoelectric elements of various sections in terms of minimising vibration sensitivity.

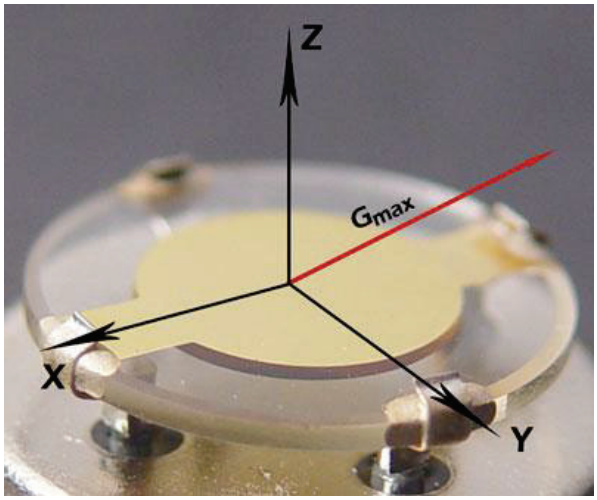

Fig. 2. An example of a piezoelectric element fixed at four points with minimal vibration sensitivity

The calculation method for circular piezoelectric elements with three or more mounting points is as follows. The initial stress and displacement fields at each point in the plane of the quartz plate are determined as a function of the plate orientation, acceleration direction and location of the attachment points. Then, equations are derived that relate the displacements for thickness-shear and bending vibrations through elastic constants and calculate the changes in the frequency of thickness-shear vibrations, which are presented in the form

$$\Delta f/f = S(\varphi,\ \gamma;\ \theta,\ \phi;\ D/b,\ n_{kp},\ \alpha_k;\ G), \qquad (9)$$

i.e., a function of the azimuthal angleψ formed by the acceleration vector relative to the crystallographic axis X and the angle of the siteγ , the acceleration G and the slice (θ,φ) , the ratio D/b (diameter to thickness of the piezoelectric element), the number of attachment points n_{kp} and the angle $\alpha_k (K = \overline{1, n_{kp}})$, determining the position of the attachment point relative to the X axis.

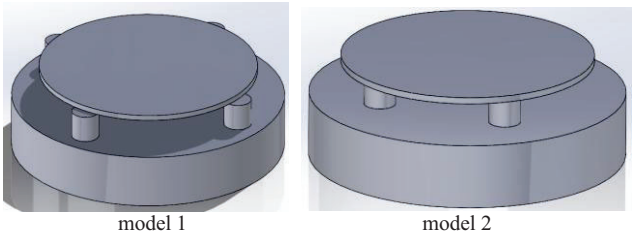
Classical models of piezoresonant systems typically rely on linear second-order differential equations to describe the fundamental oscillatory behavior of quartz resonators [13, 14]. These models assume a single dominant mode of vibration, with the system treated as a damped harmonic oscillator:

$$mx^{\cdot\cdot} + cx^{\cdot} + kx = F(t)m, \qquad (10)$$

Where m is the effective mass, c is the damping coefficient, k is the stiffness, and $F(t)$ is the external force or excitation. While adequate for single-mode analysis and low-amplitude

operation, such models inherently neglect multifrequency interactions and nonlinear effects present in real-world scenarios.

To account for multiple resonant frequencies, some models extend the single-degree-of-freedom (SDOF) approach to multi-degree-of-freedom (MDOF) systems. These represent the resonator as a system of coupled oscillators, each corresponding to a vibrational mode [15].



While these models provide insight into mode superposition and coupling, they remain predominantly linear and often exclude nonlinear modal interactions, mode hopping, or internal resonance—phenomena that play crucial roles under vibrational destabilization.

Despite the progress in modeling techniques, existing approaches suffer from several key limitations when applied to multifrequency piezoresonant systems [16]:

- Inadequate representation of internal resonances and nonlinear modal interactions;
- Neglect of environmental destabilizing factors, such as random vibrations or temperature-induced parameter drift;
- Oversimplified boundary conditions, which fail
- to represent the real mounting and excitation conditions of quartz elements;
- Lack of integration between electromechanical and thermomechanical modeling, which is essential for precision applications.

These shortcomings hinder accurate prediction and control of multifrequency behavior in resonators used in high-stability oscillators and sensors. [17] Therefore, there is a critical need for more comprehensive modeling frameworks that combine mechanical, electrical, and nonlinear dynamic effects.

Two 3D-model of an 8 mm piezoceramic disk with four-point support for studying multi-frequency oscillations was developed for further research by SolidWorks. “Model 1” and “model 1”are shown in Fig.3

model 1 model 2

Fig. 3. Models of a system for studying multi-frequency oscillations

A finite element model of the piezoelectric device was developed. The simulation results obtained resonant frequencies, which showed in fig.4 and fig.5.

Fig. 5. Calculated resonant frequencies of a piezoelectric device in SolidWorks (geometric model 2)

The results of the stress analysis of the quartz holder and piezoelectric element system in SolidWorks [18], which is an important step in optimizing the design of piezoelectric devices, are presented in Fig. 6. To compare the influence of the quartz holder design on the dynamic properties of the resonator, models with different numbers of mounting points were investigated, with a maximum mounting location error of 1^0. The obtained natural frequencies for “model 1” are shown in Fig 6 and Fig.7. The obtained natural frequencies for “model 2” are shown in Fig 8 and Fig.9.

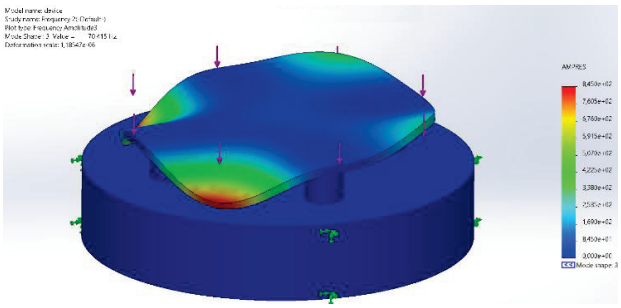

Fig. 9. Stress analysis of a piezoelectric device in the SolidWorks Simulation with for 4-point mounting – pattern of mechanical stress distribution for Frequency for "model 2"

Following the modeling, the acquired normalized mechanical stress field serves as the foundation for computing the vibromechanical frequency shifts of the quartz resonator.

Simulation for "model 2" was also carried out in the COMSOL Multiphisics. The obtained values of stresses arising during the operation of the piezoelectric device are shown in Fig. 10. Calculated oscillation data similar to the results obtained from SolidWorks Simulation.

The use of COMSOL Multiphysics enabled accurate identification of eigenmodes and resonance behavior in an 8 mm piezoceramic disk with four-point support. The results confirm that standard low-frequency excitation fails to activate the system's dynamic response and highlight the importance of resonant frequency targeting. The presence of multiple closely spaced resonance modes suggests a complex interaction that requires refined modeling to ensure stability in practical applications.

Conclusions

The research presented in this paper focused on the modeling and simulation of multifrequency piezoresonant systems, emphasizing the impact of vibrational destabilizing effects and structural mounting configurations. A detailed review of classical and advanced mathematical models highlighted the limitations in capturing complex dynamic behaviors typical of quartz and piezoceramic resonators. A finite element model of an 8 mm piezoceramic disk with four-point support was developed and analyzed using both SolidWorks and COMSOL Multiphysics. The simulation results revealed multiple resonant frequencies and confirmed the influence of support design and frequency selection on mechanical stress distributions. These findings underscore the need for refined modeling strategies that integrate nonlinear dynamics, environmental variability, and practical design constraints. The proposed modeling approach provides a robust foundation for the development of vibration-resistant piezoresonant devices, with potential applications in reference oscillators, MEMS, and precision sensing systems.

***Abstract* — With the increasing complexity of modern technical systems, such as wheeled and tracked vehicles, there is a growing need for adequate diagnostic methods that can take into account not only structural but also temporal dependencies between components. This paper looks at using structural automata algebra as a formal tool for describing, analyzing, and predicting the behavior of complex systems, taking into account the temporal coordination of signals. It highlights the importance of considering temporal characteristics when diagnosing failures caused by cascading processes and interactions between elements. The theoretical foundations for the construction of structural automata, their composition, and conditions for correct functioning are presented. Particular attention is paid to the problems of mismatch between abstract and real signal processing times, which requires refinement of the rules for constructing diagnostic models. The proposed approach demonstrates its versatility and applicability to a wide class of mechatronic, energy and transport systems, ensuring the transition to predictive maintenance and increased operational reliability.**

Keywords* — *predictive diagnostics, structural automata, temporal signal coordination, technical condition, composition of automata, logical-dynamic connections, mathematical modelling, failure, automata algebra

I. Introduction

Modern trends in the development of mechanical engineering are characterized by an increase in the complexity of technical systems, which is due to the need to improve their reliability, functionality and operational efficiency. Wheeled and tracked vehicles, as examples of heavy-duty and multifunctional objects, fully demonstrate the general problem: diagnosing their technical condition requires not only in-depth engineering expertise, but also the use of adequate mathematical models capable of taking into account the complex logical and dynamic relationships between system elements.

The relevance of developments in the field of structural and temporal diagnostics is due to both the rapid development of intelligent control systems and the need to improve the accuracy of real-time fault detection. Traditional methods based on static or quasi-static models do not provide the required level of sensitivity and temporal resolution when detecting faults in systems with a high degree of interaction between components. In this context, the use of structural automaton algebra as a formalism that allows for the rigorous description of discrete-continuous processes characteristic of the functioning of complex technical objects becomes particularly important.

A key direction in modern technical diagnostics is predictive analysis of technical condition, based on forecasting the development of potential failures long before they actually occur. This approach minimizes downtime, optimizes maintenance and improves the overall economic efficiency of equipment operation. Predictive diagnostics requires mathematical models that take into account not only current signals, but also their temporal dynamics and interrelationships. In this respect, the use of structural automata, taking into account the temporal consistency of signals, provides an effective tool for formalizing, monitoring and predicting the behavior of complex technical systems.

An additional factor that reinforces the need to develop new approaches is the temporal consistency of diagnostic signals, a parameter that is often ignored in classical diagnostic models but is critical when analyzing failures resulting from the cascading influence of components on each other. The use of structural automata, taking into account time constraints, allows not only to formalize the structure of the system and the connections between its nodes, but also to reflect real cause-and-effect relationships over time, which significantly increases the reliability, speed and predictive power of diagnostic solutions.

The proposed approach is universal and applicable not only to wheeled and tracked vehicle systems, but also to all

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

mechanical and mechatronic industries, from aviation and power plants to numerically controlled machine tools and robotic systems. Thus, the creation and development of diagnostic methods based on structural automaton algebra, taking into account the temporal coordination of signals, is a promising scientific direction that is in demand in a wide range of modern engineering and technology industries and ensures the transition to a new generation of predictive maintenance.

II. State-of-the-Art

Modern technical systems, including wheeled and tracked vehicles, are becoming increasingly complex, requiring effective methods of diagnostics and maintenance [1]. Predictive diagnostics, based on data analysis and failure prediction, is becoming a key area in ensuring the reliability and efficiency of such systems [2, 3, 4].

In recent years, there has been active development of predictive diagnostic methods using machine learning and time series analysis [5–9]. For example, in [10], a predictive maintenance system for armored vehicles was proposed, based on an ensemble of machine learning models, including Light Gradient Boosting and Random Forest, which made it possible to achieve high accuracy in predicting technical condition.

Structural automaton algebra provides a formal approach to modelling and analyzing complex technical systems [11]. In [12], a digital twin for civil engineering structures is proposed, using probabilistic graphical models and dynamic Bayesian networks to account for uncertainty and temporal consistency of signals. This allows real-time diagnostics of the condition of structures and optimization of maintenance planning.

The temporal consistency of signals plays an important role in the accuracy of technical system diagnostics [13, 14]. In [15], a method is presented for determining the location of damage in mechanical structures using a multi-purpose global pattern search, which allows temporal aspects of signals to be taken into account and improves the accuracy of damage localization. Also, [16] describes a computational framework for real-time diagnostics and condition prediction of aircraft propulsion systems, emphasizing the importance of considering the temporal characteristics of signals to improve the accuracy of residual life estimation.

Predictive diagnostics is used not only in the transport industry, but also in other areas. [17, 18] look at using predictive maintenance in agricultural vehicles using telemetry, maintenance history, and geospatial data, showing how versatile this approach is. In addition, [19–22] discuss intelligent maintenance systems and predictive manufacturing, emphasizing the role of machine learning [23] and the Internet of Things in the implementation of predictive diagnostics in industry.

Thus, the integration of structural automaton algebra and the consideration of signal time coordination in predictive diagnostics of complex technical systems, including wheeled and tracked vehicles, represents a promising direction of research that contributes to improving the reliability and efficiency of equipment operation.

III. Problem Statement

Let us introduce the algebra of structural automata. The system of operations F allows us to describe the structure and laws of functioning of a fairly broad class of real systems. Applying any element $c \in C$ of any finite sequence of operations $F = \{f_1^1, f_2^1, ..., f_9^1, f_{10}^1\}$ from a set of operations to any element results in a composition that is an automaton. However, the result of applying some elements $c \in C$ of finite sequences of operations $F = \{f_1^1, f_2^1, ..., f_9^1, f_{10}^1\}$ from a set of operations to some elements is not an automaton.

Indeed, let $(f_{10}^2 c_1 ... c_k, c)$ is some structural automaton. It is obvious that any term $f_l f_{f-1} ... f_1 f_{10}^2 c_1 ... c_k$ defines a structural automaton. A formal expression of the form $\overline{f}_l f_{l-1} ... \overline{f}_1 f_{10}^2 c_1 ... c_k$, where $\overline{f}_i \in F^*$, $1 \le i \le l$, also defines a certain composition of elements c_1, c_2, …, c_k. If in this composition the operation f_9^1 is applied in the variant $f_{9,1}^1$, in the case where the first output node depends on the first input node, then the result of the composition will not be an automaton (in the sense accepted in abstract automaton theory). We cannot calculate the values of functions δ and λ, which depend on δ_1, …, δ_k, λ_1, …, λ_k, knowing the input signal to the composition and the states of all elements c_1, c_2, …, c_k.

Usually, the abstraction of discrete automata time is extended to automata of the form

$$c = (S, X^n, X^m, \delta, \lambda), \quad (1)$$

where $S \subset X^i$ for some finite i; n, m are non-negative integers; $\delta : S \times X^n \to S$ and $\lambda : S \times X^n \to X^m$ are mappings.

Because of this, each automaton c_i operates in discrete time, taking non-negative integer values 0, 1, 2, …, t. Based on this, the conditions for the correct construction of diagrams are defined. With the accepted agreements on a single operating time, any composition of automata and each elementary automaton of the composition process the input signal in the same abstract time interval. Consequently, signals must arrive simultaneously at both inputs of the automaton c_2 in the composition shown in Fig. 1.

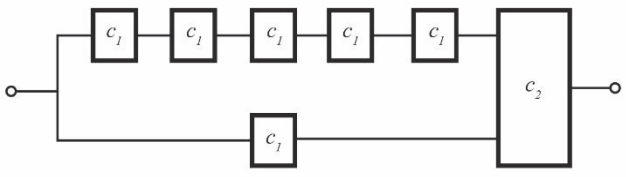

Fig. 1. Automatons layout

In practice, the processing time of an input signal by a real system R differs from the processing time of an input signal by a sequential connection of a series of such systems. In this regard, it is necessary to consider other possible abstractions of discrete automatic time that more fully account for the properties of real systems.

To fully appreciate the difficulties that arise here, let us consider some examples. Let us take two elements,

$$c_i = (S_i, X^2, X^2, \delta_i, \lambda_i),\ i = 1,2, \qquad (2)$$

which are structural automata (c_1, c_1) and (c_2, c_2) in the algebra A_C.

Let us construct a sequential composition of these structural automata, shown in Fig. 2, which is described by the term

$$T = (f^1_{9,1})^2 (f^1_4)^2 f^2_{10} c_1 c_2. \qquad (3)$$

The structural automaton c defined by the term T has the form

$$\begin{gathered} c = (S_1 \times S_2, X^2, X^2, \delta, \lambda), \\ \delta((s_1,s_2),(x_3,x_4)) = (\delta_1(s_1,(pr_1\lambda_2(s_2,(x_3,x_4)), \\ pr_2\lambda_2(s_2,(x_3,x_4)))), \delta_2(s_2,(x_3,x_4))), \\ \lambda((s_1,s_2),(x_3,x_4)) = \lambda_1(s_1,(pr_1\lambda_2(s_2,(x_3,x_4)), \\ pr_2\lambda_2(s_2,(x_3,x_4))). \end{gathered} \qquad (4)$$

However, the transition δ and exit λ functions are not always defined by formulas (4).

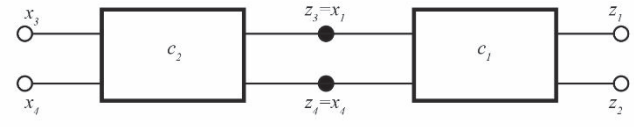

Fig. 2. Sequential composition of automatons

Suppose that structural automata (c_i, c_i), to whose inputs input signals are applied at time t, produce output signals at time $t + k_j$, $j = 1,2$. If $k_2 \geq k_1$, and signals are applied to input nodes x_3 and x_4 at intervals of no less than k_2, then δ and λ of the structural automata (T, c) will be determined by formulas (4). When $k_2 < k_1$, and signals are applied to input nodes x_3 and x_4 at intervals equal to k_2, the laws of operation of the sequential connection, in general, do not correspond to formulas (4). Indeed, applying input signals to nodes x_3 and x_4 at times $t + nk_2$, where $n = 0,1,2,...$, ensures that signals are applied to nodes x_3 and at times $t + nk_2$, where $n = 1,2,3...$. However, the structural automaton (T, c) outputs a signal corresponding to the input signal applied at time $t + k_2$ to the input signal at time $t + k_2 + k_1 > t + 2k_2$. Consequently, the next input signal to the structural automaton (c_1, c_1) arrived during signal processing. The automaton's response (T, c) to an input signal that arrived 'early' will not necessarily be described by formulas (4).

To solve diagnostic and control problems, it is necessary to describe the compositions of not only serviceable but also faulty structural automata. Let the structural automaton (c_2, c_2) output nodes z_3 and z_4 signals in the form of pulses. Then a signal delay at one of the nodes, for example at node z_3, will lead to the input signals $(e, pr_2\lambda_2(s_2(x_3, x_4)))$ being fed to the input nodes of the automaton (c_1, c_1). In this case, the structural automaton (T, c) described by term (3) has the following laws of operation, which differ from (4):

$$\begin{gathered} \delta((s_1,s_2),(x_3,x_4)) = (\delta_1(s_1,(e, pr_2\lambda_2(s_2,(x_3,x_4)))), \\ \delta_2(s_2,(x_3,x_4))), \\ \lambda((s_1,s_2),(x_3,x_4)) = \lambda_1(s_1,(e, pr_2\lambda_2(s_2,(x_3,x_4)))). \end{gathered} \qquad (5)$$

Thus, after identifying the first output node and the first input node by operation f^1_9, the laws of operation are not always determined by formulas of the form

$$\begin{gathered} f^1_{9,1}c = (S, X^{n-1}, X^{m-1}, f^1_{9,1}\delta, f^1_{9,1}\lambda), \\ \forall_{(s,\bar{x})}(f^1_{9,1}\delta(s,\bar{x}) = \delta(s,(pr_1\lambda(s,(e,\bar{x})),\bar{x})) \wedge \\ \wedge f^1_{9,1}\lambda(s,\bar{x}) = pr_{2...m}\lambda(s, pr_1\lambda(s,(e,\bar{x})),\bar{x}))). \end{gathered} \qquad (6)$$

$$\begin{gathered} f^1_{9,2}c = (S \times X, X^{n-1}, X^{m-1}, f^1_{9,2}\delta, f^1_{9,2}\lambda), \\ \forall_{((s,x),\bar{x})}(f^1_{9,2}\delta((s,x),\bar{x}) = \delta(s,(x,\bar{x})), pr_1\lambda(s,(x,\bar{x}))) \wedge \\ \wedge f^1_{9,2}\lambda((s,x),\bar{x}) = pr_{2...m}\lambda(s,(x,\bar{x}))). \end{gathered} \qquad (7)$$

More precisely, if the connection between the operation f^1_9 and the transformation of transition and output functions is not specified in the algebra of structural automata, then a term T containing the operation f^1_9 may describe a composition that is not an automaton. This means that the value of the term T may be undefined on the set C. Therefore, a structural automaton is defined as a pair – a term and its value. This allows us to consider compositions described by universally defined terms in the algebra of structural automata.

Let us find sufficient conditions that guarantee that each functional symbol f^1_9 in a term T corresponds to a transformation of transition and output functions according to formulas (6) and (7). The subject of analysis should be the temporal consistency of the occurrence of signals at the nodes. However, finding such admissible conditions without specifying the class of systems under study is difficult, so it is necessary to introduce restrictions on the systems under consideration.

First, let us clarify the problem using an example and outline ways to solve it. Let the structural automata (c_i, c_i), $i = \overline{1,5}$, be connected according to the diagram shown in Fig. 3.

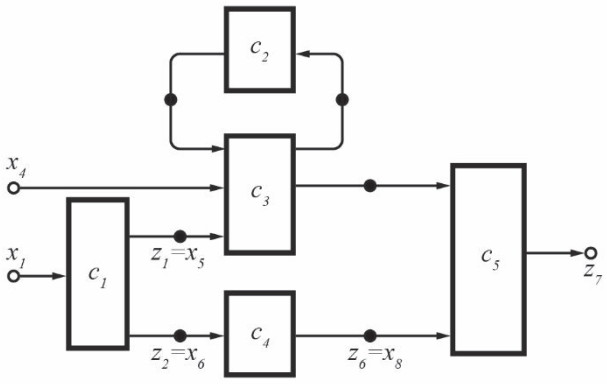

Fig. 3. Automatons composition

Suppose that the automata c_i are defined by transition and output tables. Let us express the transition δ and output λ

functions of the composition through the transition δ_i and output λ_i functions of the original elements. Let us find a term T describing the composition. Figure 2 shows the designations of the input and output nodes. The nodes that must be identified are connected by equal signs. There are six pairs of nodes that are to be identified: (z_4, x_2), (z_3, x_3), (z_1, x_5), (z_2, x_6), (z_5, x_7), (z_6, x_8). Let us find a term describing the identification of the output node z_4 and the input node x_2. Such identification is preceded by obtaining a parallel connection of the automata and shifting the input node x_2 and the output node z_4 to the places of the first nodes.

Abbreviation used

$$f_{10}^2(...(f_{10}^2(f_{10}^2 c_1 c_2)c_3)...)c_n = f_{10}^2 c_1 c_2 c_3 ... c_n \ . \qquad (8)$$

Then the identification of nodes z_4 and x_2 is described by the term $T_1 = f_{9,1}^1 (f_4^1)^3 f_2^1 f_{10}^1 c_1 c_2 c_3 c_4 c_5$. The identification of nodes z_1, x_5 and z_2, x_6 leads to the term $T_2 = (f_{9,1}^1)^2 (f_4^1)^3 (f_2^1)^2 T_1$. To describe the identification of nodes z_5, x_7 and z_6, x_8 it is sufficient to apply the operation f_4^1 and twice the operation f_9^1, the operation $f_{9,2}^1$ and f_2^1.

As a result, we obtain a term describing the composition in Fig. 3. The initial and final stages of the composition are shown in Fig. 4:

$$T = f_2^1 f_{9,2}^1 f_2^1 f_4^1 (f_{9,1}^1)^2 f_4^1 (f_{9,1}^1)^2 (f_4^1)^3 (f_2^1)^2 f_{9,1}^1 (f_4^1)^3 f_2^1 f_{10}^2 c_1 c_2 c_3 c_4 c_5 \quad (9)$$

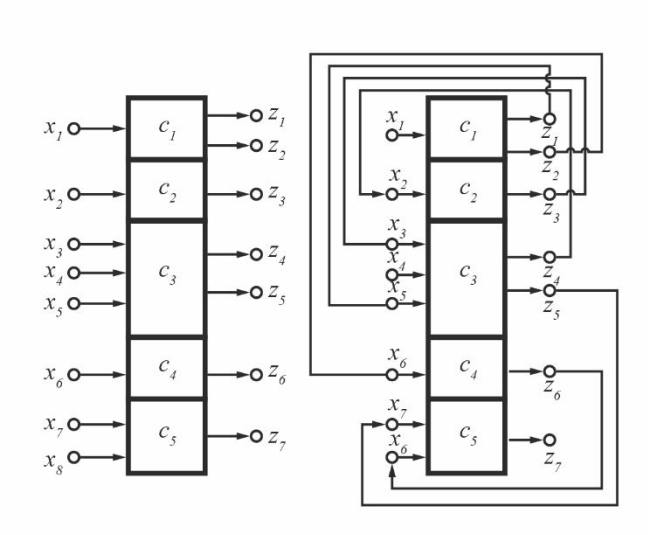

Fig. 4. The initial and final stages of the composition of automatons

In the term T, the operation f_9^1 is reflected taking into account its variants, so we can write down how the transition-output functions δ and λ the result of the composition are expressed through the transition-output functions δ_i and λ_i the initial structural automata.

For parallel connection, it is easy to write down δ and λ as state functions s_1, s_2, …, s_5, and input signals x_1, x_2,…, x_8 of the initial automata c_1, c_2,…, c_5:

$$\begin{aligned} \lambda &= \lambda(\lambda_1, \lambda_2, \lambda_3, \lambda_4, \lambda_5, (s_1, ..., s_5), (x_1, x_2, ..., x_8)), \\ \delta &= \delta(\delta_1, \delta_2, \delta_3, \delta_4, \delta_5, (s_1, ..., s_5), (x_1, x_2, ..., x_8)). \end{aligned} \qquad (10)$$

Operations f_2^1 and f_4^1 are auxiliary; they are necessary for formalizing the process of describing the structure. Their influence on the transition and output functions is reduced to swapping the places of the arguments and swapping the places of the output function values.

The transition and output functions undergo significant changes under the influence of operation f_9^1. Thus, as a result of identifying the output node z_4 and the input node x_2, we obtain

$$\begin{aligned} \lambda &= \lambda(\lambda_1, \lambda_2, \lambda_3, \lambda_4, \lambda_5, (s_1, ..., s_5), (x_1, x_3, x_4, ..., x_8)), \\ \delta &= \delta(\delta_1, \delta_2, \delta_3, \delta_4, \delta_5, (s_1, ..., s_5), (x_1, x_3, x_4 ..., x_8)). \end{aligned} \qquad (11)$$

The transformations defined by the sequence of operations $(f_4^1)^3 (f_2^1)^2$ and of an auxiliary nature are applied to the equalities (11). The identification of the output node z_1 and the input node x_5 is reduced to substituting the expression $pr_1 \lambda_1 (s_1, x_1)$ for the symbol x_5 in (11), and the identification of the output node z_2 and the input node x_6 is reduced to substituting the expression $pr_2 \lambda_1 (s_1, x_1)$ for the symbol x_6 in (11). As a result, we obtain

$$\begin{aligned} &\lambda = \lambda(\lambda_1, \lambda_2, \lambda_3, \lambda_4, \lambda_5, (s_1, ..., s_5), (x_1, x_3, x_4, x_7, x_8)), \\ &\delta = \delta(\delta_1, \delta_2, \delta_3, \delta_4, \delta_5, \lambda_1, \lambda_3 (s_1, ..., s_5), (x_1, x_3, x_4, x_7, x_8)). \end{aligned} \qquad (12)$$

Identifying nodes z_5 and x_7 with nodes z_6 and x_8 reduces the transition and output functions to the following form:

$$\begin{aligned} &\lambda = \lambda((\lambda_1, ...\lambda_5), (s_1, ..., s_5), (x_1, x_3, x_4)), \\ &\delta = \delta((\lambda_1, \lambda_3, \lambda_4), (\delta_1, ..., \delta_5), (s_1, ..., s_5), (x_1, x_3, x_4)). \end{aligned} \qquad (13)$$

Now we need to take into account the transformation under the action of the operation $f_{9,2}^1$. To do this, we need to substitute in (13) instead of the expression x_3

$$\lambda_2 (s_2, pr_1 \lambda_3 (s_3, (x_3, x_4, pr_1 \lambda_1 (s_1, x_1)))) \qquad (14),$$

which also contains the symbol x_3. Such substitutions can be made in (13) everywhere except for the substitution in the expression itself. Therefore, we will supplement the laws of operation with an equality, using which we can determine the signal in the intermediate node x_3, which allows us to characterize the signal in this node as a memory component. Finally, for the transition and output functions of the structural automaton, we obtain the following dependencies

$$\begin{aligned} &\lambda = \lambda((\lambda_1, ...\lambda_5), (s_1, ..., s_5, s_6), (x_1, x_4)), \\ &\delta = \delta((\lambda_1, \lambda_3, \lambda_4), (\delta_1, ..., \delta_5), (s_1, ..., s_5, s_6), (x_1, x_4)). \end{aligned} \qquad (15)$$

From equations (15), it follows that to determine the output signal at a node z_7, it is necessary to know the signals at nodes x_1 and x_4, the states s_1, s_2, s_3, s_4, s_5 and the signal at the intermediate node x_3. The structural automaton (T, c) in Fig. 3 has nine nodes. Consider the transformation of input signals by the structural automaton (T, c), starting at

time t. During the operation of the automaton, signals will appear in the nodes, generally speaking, in each i node at its $(t+\tau_j)$ own time.

Let us make a number of assumptions about the properties of the systems under consideration, which facilitate the study of the coordination of signal occurrence in nodes, but naturally narrow the class of real systems to which the description in the form of a structural automaton can be applied.

1. In each node, a signal occurs instantaneously at some moment of abstract time.

2. At each node, at each moment of abstract time, no more than one signal can occur (i.e., be applied, issued). This assumption does not mean that several signals cannot be applied to a node at the same time. However, in this case, a total signal must be formed, which is an element of the permissible set of signals.

The restriction defined by the following assumption is essential.

3. During the entire process of processing signals applied to external input nodes (such a process is assumed to be finite), a signal occurs only once in each node. A signal that occurs in a node at a moment of time t can be stored until a certain moment $t+\tau$, where $\tau = 0,1,2,...$

4. In each node of the structural automaton, signals of one of the following types arise: non-stored signals, which arise at a certain moment of abstract time and only at that moment; stored signals, which, having arisen at a certain moment of abstract time, remain in the node until the moment of the next signal arising in this node.

Assumptions 1-4 impose restrictions on the values τ_j characterizing the moments of occurrence of signals in the nodes of the structural automaton. In addition, restrictions on the values τ_j are imposed by formulas (15). Let us denote each node of the structural automaton (T,c) by a number coinciding with the index of the symbol x_i corresponding to this node, and node z_7 by number 9. Let us analyze formulas (15) taking into account the composition in Fig. 3.

It is obvious that $\tau_9 \geq \tau_j$, $j = 1,2,...,8$ since to determine the signal in node 9, it is necessary to know the signals in nodes 1–8. Each value of the output function, or the projection of the output function value, corresponds to the signal in the node. The values of the output function arguments are interpreted as the values of the signals in the nodes preceding the values of the signals in the nodes corresponding to the value of the output function. Therefore, from the expression $\lambda_1(s_1,x_1)$ we obtain $\tau_5 \geq \tau_1$ and $\tau_6 \geq \tau_1$.

Similarly, the following relationships are established:

$$\tau_3 \geq \tau_2,\ \tau_2,\ \tau_7 \geq \tau_3,\ \tau_4,\ \tau_5,\ \tau_8 \geq \tau_6,\ \tau_9 \geq \tau_7,\ \tau_8. \quad (16)$$

From assumption 3, it follows that the signal at node 3 occurs during signal processing only once at the moment $t+\tau_3$, where $\tau_3 \leq \tau_2$.

The relationship $\tau_3 \geq \tau_2$ is related to the change in memory state, since the signal at node 3 is considered as a component of the memory state vector. As a result of the analysis, we obtain two systems of relationships:

$$\tau_5,\ \tau_6 \geq \tau_1,\ \tau_7 \geq \tau_3,\ \tau_4,\ \tau_5,\ \tau_8 \geq \tau_6,\ \tau_9 \geq \tau_7,\ \tau_8, \quad (17)$$

$$\tau_5,\ \tau_6 \geq \tau_1,\ \tau_2,\ \tau_7 \geq \tau_3,\ \tau_4,\ \tau_5,\tau_8 \geq \tau_6,\ \tau_9 \geq \tau_7,\ \tau_8,\ \tau_3^* \geq \tau_2. \quad (18)$$

IV. CONCLUSION AND FUTURE WORK

The system of inequalities (17) provides rough estimates for the moments of occurrence of signals in nodes during the formation of the output signal. The system of inequalities (18) provides estimates for the moments of occurrence of signals in nodes during the formation of the next state. These two systems do not contradict each other.

Thus, formulas of the form (15) impose restrictions on the moments of occurrence of signals in the nodes of the structural automaton (T,c). However, the systems of inequalities (17) and (18) do not determine specific values of τ_j, $j = \overline{1,9}$. The determination τ_j is related to the consideration of specific objects described by the structural automaton (T,c), or the addition of new restrictions.

Suppose that for some real object, numbers τ'_j, $j = \overline{1,9}$, satisfying the systems of inequalities (17), (18) are defined, and the transition and exit functions of the structural automaton describing this object are determined by formulas of the form (15).

Let a malfunction occur in the object, expressed by the fact that at a certain node, for example node 7, a signal occurs at time $\tau''_7 \neq \tau'_7$. Even if the parts of the object are again described by structural automata (c_i,c_i), $i = \overline{1,5}$, and their composition by term T, the transition and output functions of the entire composition may not be defined by formulas of the form (15). The signal at node 9 (at the output z_7) at $\tau''_7 \neq \tau'_7$, depending on the properties of the real object, can be determined not only by formulas (15), but also by three other possible formulas:

$$\begin{gathered}\lambda = \lambda'((s_1,...,s_5,s_6),(x_1,x_4)),\\ \lambda = \lambda''((s_1,...,s_5,s_6),(x_1,x_4)),\\ \lambda = \lambda'''((s_1,...,s_5,s_6),(x_1,x_4)),\\ \lambda' \neq \lambda'' \neq \lambda'''.\end{gathered} \quad (19)$$

In some cases, the occurrence of a signal in node 7 ‘at the wrong time’ can be described by applying certain symbols and to nodes 7 and 8, x'_7 and x'_8 in some cases it cannot be described at all by the selected means of description.

***Abstract*—This study focuses on the application of Data Science and Machine Learning (ML) techniques to predict joint strength in electric resistance butt welding of steel open-sections used in metal-plastic window systems. The main goal is to identify and model the relationships between welding parameters (electrical current strength, welding time, and strip thickness) and the resulting weld seam strength. Given the sparse nature of the available experimental data, advanced data preprocessing was performed using Python libraries such as Pandas and Scikit-learn, including noise reduction and error correction. Several models were developed, including second- and fourth-degree polynomial regressions and a multilayer perceptron (MLP), to capture nonlinear dependencies between process variables. The fourth-degree polynomial regression model proved to be the most accurate among traditional approaches, while the MLP achieved even higher prediction performance. These models enable not only accurate strength forecasting, but also support the intelligent selection of welding parameters in production environments with constrained data. The presented approach lays the groundwork for integrating adaptive ML systems into welding process control, facilitating real-time decision-making and technological optimization.**

Keywords—Data Science, machine learning, predictive modeling, electric resistance welding, sparse data, polynomial regression, MLP, process optimization, Python, Scikit-learn.

I. Introduction

In the production of reinforcing bent open-sections for metal-plastic windows, butt welding of strip material is used to improve material efficiency [1, 2]. These profiles, which serve as structural elements of window frames, must meet increased strength requirements. For their production, galvanized steel from coils of varying thicknesses (t) is used. To reduce waste, the end of one coil is butt-welded to the beginning of the next [3, 4]. The durability of this weld is critical and depends on parameters such as welding current (I), heating time (τ), strip width, surface cleanliness, and butt-end preparation [4–6]. To determine optimal welding settings, experiments with varying parameters were conducted, and the results were analyzed using regression modeling and machine learning. In many practical cases, the selection of welding parameters and prediction of seam strength must be performed under limited data conditions, which necessitates the use of adaptive and data-efficient modeling approaches.

II. Review of the Latest Research and Publications

Various methods for producing reinforced open-sections, such as U-channel profiles, include extrusion or die bending [7]. These methods rely on precise trimming and adequate pressing force (P), along with proper die design, to reduce deformation errors [8, 9]. Roll-forming, which involves multi-pass bending of strip material, causes significant plastic deformation and requires careful control of upsetting depth during butt welding [10, 11]. Copper-electrode welding machines are used and demand proper edge preparation and surface cleaning. Fig. 1 shows a typical contact electric butt-welding machine.

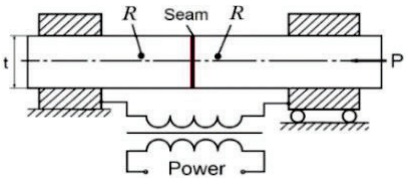

Fig.1. Electric butt-welding machine.

Maintaining edge parallelism is essential, especially as strip width increases. Proper adjustment of the welding machine involves balancing electrical and mechanical systems, using experimental methods to optimize parameters under various influencing factors [12]. During the operation of the butt-welding machine, the ends of the strips are heated by the flow of electric current I_w through them. This current, flowing through the total electrical resistance R of the strip ends, generates heat Q, which is regulated by Joule-Lenz's law [13]:

$$Q = I_w^2 * R * \tau, \quad (1)$$

where τ – welding time.

The total electrical resistance of the joining ends is determined by the expression:

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

$$R = 2R_p + R_c, \quad (2)$$

where R_p – The resistance of the strip ends (the protrusion of the strip ends from the machine electrodes) is determined by the expression, R_c – the contact resistance between the ends of the strips.

During the high-temperature regime, when the ends of the strips are heated to 600-700 °C, the contact resistance is relatively high. However, once this temperature is reached, the contact resistance is practically eliminated, and further heating of the components occurs due to their inherent electrical resistance. The presence of contact resistance is associated with the limited area of electrical contact due to the uneven surface of the components, as well as the presence of oxide and hydroxide films, moisture, oils, corrosion products, dust, and other contaminants. The contact resistance of the components decreases with an increase in upsetting (compression stage increasement).

The quality of the welded joints of wide strips was checked both destructively (through external inspection) and destructively after roll-forming [4]. For destructive testing, samples were cut from the flanges and web of the roll-formed U-section and subjected to tensile testing [4]. On the fig.2 a scheme of samples retrieving is depictures including the locations and form of samples cut from flanges and base.

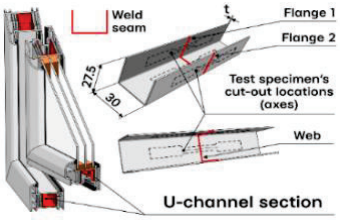

Fig. 2. Sample cutting scheme.

The limited amount of data requires finding suitable equations but the challenge in it lies in the high likelihood of overfitting, the limitation of model complexity despite the potential complexity of the actual dependency, high sensitivity to random outliers and deviations, and a critical dependence on the selected parameters, especially in cases where the relevance of each is unknown [14–15]. In this regard, an important task involves detecting and removing noise from experimental data using machine learning methods like collective, single, and distance-based approaches (including density and clustering). Literature mentions ignoring, filtering, or substituting noise, aiming to balance noise removal and data retention. Denoising was done using classic anti-aliasing methods [16].

III. The Purpose of the Work

The purpose of the study is to perform analysis and computer modeling to derive regression equations linking the strength of steel U-sections to welding process parameters, based on experimental data.

IV. Description of the Experiment

This experiment aimed to figure out the dependence of the strength of the reinforcing steel section on the parameters of the welding process. During the study, samples with transverse welds, cut from the base and flanges of the U-section, as well as reference samples without welds, were used. Testing was conducted using a universal testing machine (nominal force of 20 tons). The strength of each flange and the base was evaluated separately under different geometric conditions at the edge joints, which became more non-parallel as the width of the initial strip increased. These elements may show varying strength characteristics, even when welded using the same equipment settings.

The collected data were documented in a table for subsequent analysis [4]. The testing revealed that the strength of the weld joint is significantly influenced by the welding parameters and the duration of load application. Furthermore, even with consistent welding parameters, the strength varied with the thickness of the weld joint. This observation is supported by the fact that some samples failed along the weld seam, while others failed within the body of the sample, indicating either the adequacy or inadequacy of the selected welding parameters.

V. Processing Data with Data Analysis Methods

The experimental data were not suitable for regression modeling using standard Data Mining methods (Fig. 3). Due to poor structure, the data required cleaning and transformation to enable pattern recognition. Processing involved multiple stages, including error detection and noise reduction. A major challenge was the limited data volume and the inability to perform further experiments on the same equipment. Thus, methods resilient to noise and effective with small datasets were necessary.

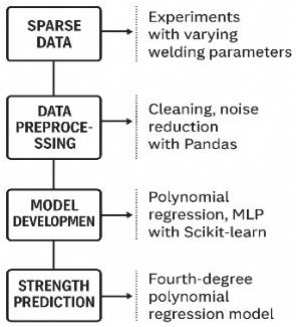

Fig. 3. Research flow diagram.

The Pandas library in Python was used as the computational platform [17]. It enabled initial data cleaning and deeper analysis without relying on external mathematical packages. The data were structured in tabular form and imported as a CSV file. Analysis results were visualized using 2D plots showing the relationship between parameters and strength coefficient. Fig. 4 illustrates the dependence of strength coefficient on weld seam thickness, excluding other factors such as time and current.

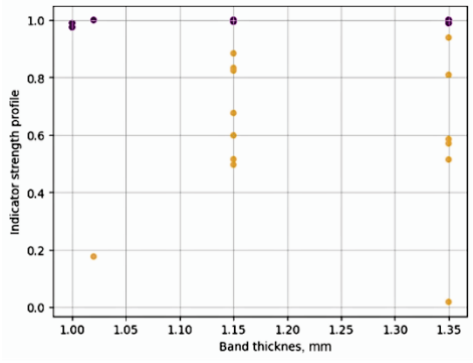

Fig 4. Diagram of the dependency of the quality of the weld seam.

Based on the data comparisons, it was determined that the dataset doesn't show a direct functional dependence on a

single parameter. Consequently, there a need to formulate hypotheses appeared, on which regression analysis methods were applied to uncover patterns within the dataset.

The initial hypothesis proposed was that a logistic regression could elucidate the dependence of strength on one or more process parameters. Given that logistic regression requires one or more parameters to vary discretely, it was most likely to identify a pattern between the strength coefficient and the welding parameters [18]. A logistic regression curve was constructed for the welding parameters, as illustrated in Fig. 5.

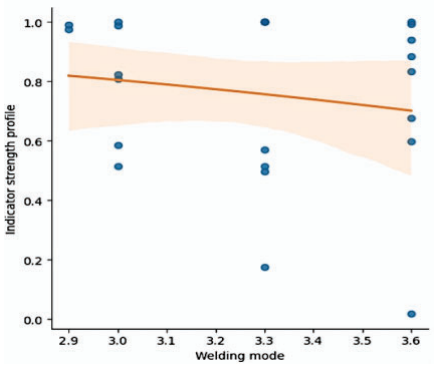

Fig. 5. Logistic regression curve for the dependence of the strength parameter on the welding mode.

To build regression models and visualize 2D dependencies, the Seaborn library in Python was used [19], offering built-in regression tools. In Fig. 4. blue dots represent experimental data, the red line shows linear regression, and the orange area indicates the uncertainty range. The resulting curves showed noticeable discrepancies—for instance, logistic regression closely resembled the linear model.

Weld joints produced under different conditions revealed distinct patterns between welding parameters and structural strength. In some cases, analyzing individual joints yielded more accurate equations than models based on the full dataset. Fig. 6 presents such a logistic regression curve, showing closer alignment with the data. However, the broader uncertainty range suggests the need for a better-suited model.

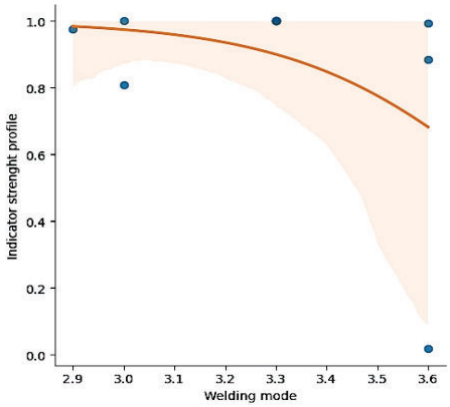

Fig. 6. Logistic regression curve for the dependence of the strength parameter on the welding mode (separately for flange 1).

Based on the performed analysis was established that isolation of the parameters doesn't allow to describe process more precisely and calculate an optimal mode for the current technological process. Therefore, it was decided to build an approximate regression equation based on all parameters.

In other words, to find regressions for the existing dataset. Since the process of finding an approximate regression equation and refining the coefficients of the variables in the equation is quite complex, it was decided to use machine learning tools, specifically the scikit-learn library in the Python programming environment [20].

Recognizing that any dependence can be approximated through regression, a linear regression model was built based on experimental data. The modeling was carried out using the scikit-learn library, allowing construction and evaluation of models with varying complexity. PolynomialFeatures generated higher-order terms, while LinearRegression fitted the transformed data. Additionally, a simple feedforward neural network was trained using scikit-learn's MLPRegressor. Its architecture and hyperparameters – number of layers, activation functions, learning rate, and regularization – were optimized via cross-validation and grid search. The neural network outperformed traditional models in capturing nonlinear patterns. Seaborn and Matplotlib supported visual analysis and result validation. This programmatic workflow ensured reproducibility, scalability, and objectivity, positioning the study as both an engineering investigation and an applied data science case.

The model in Fig. 6 was found inadequate for accurately describing the process. Despite parameter optimization, the coefficient of determination revealed notable discrepancies between predicted and actual values. To achieve more accurate analysis of the strength coefficient, a hypothesis was tested suggesting that its dependency on process parameters could be represented by a polynomial regression.

Using polynomials of varying degrees allows greater modeling flexibility and better prediction by accounting for factor interactions. To evaluate this hypothesis, polynomial regressions of degrees 2 and 4 were tested. The general form of a second-degree polynomial with three independent variables is given below:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 x_1^2 + \beta_5 x_2^2 + \\ + \beta_6 x_3^2 + \beta_7 x_1 x_2 + \beta_8 x_1 x_3 + \beta_9 x_2 x_3, \quad (3)$$

where β_0 – constant term (intercept), β_1 to β_9 – coefficients calculated by machine learning model, x_1 –weld seal thickness, x_2 – welding mode, x_3 – welding time.

With the help of sub library scikit-learn-preprocessing [21], particularly functions of preliminary optimization of polynomial model a polynomial regression model for second degree was built in order to describe the dependency of structural strengths coefficients based on three independent parameters.

$$y = 0.18507 + 7.633x_1 + 9.0942x_2 - 5.0855x_3 + \\ + 0.0122x_2^2 - 0.0006x_3^2 - 0.06x_1x_2 + 0.02x_1x_3 - \\ - 0.0156x_2x_3. \quad (4)$$

Mean squared error is 0.0173, which conforms the adequacy of the created model. In addition to this equation, a 4th-degree regression equation was constructed. The general form for 3 independent variables is as follows:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 x_1^2 + \beta_5 x_2^2 + \beta_6 x_3^2 + \\ \beta_7 x_1 x_2 + \beta_8 x_1 x_3 + \beta_9 x_2 x_3 + \beta_{10} x_1^3 + \beta_{11} x_2^3 + \beta_{12} x_3^3 + \\ \beta_{13} x_1^2 x_2 + \beta_{14} x_1^2 x_3 + \beta_{15} x_2^2 x_1 + \beta_{16} x_2^2 x_3 + \beta_{17} x_3^2 x_1 + \\ \beta_{18} x_3^2 x_2 + \beta_{19} x_1 x_2 x_3 + \beta_{20} x_1^4 + \beta_{21} x_2^4 + \beta_{22} x_3^4 + \\ \beta_{23} x_1^3 x_2 + \beta_{24} x_1^3 x_3 + \beta_{25} x_2^3 x_1 + \beta_{26} x_2^3 x_3 + \beta_{27} x_3^3 x_1 + \\ \beta_{28} x_3^3 x_2 + \beta_{29} x_1^2 x_2^2 + \beta_{30} x_1^2 x_3^2 + \beta_{31} x_2^2 x_3^2 + \beta_{32} x_1^2 x_2 x_3 + \\ \beta_{33} x_1 x_2^2 x_3 + \beta_{34} x_1 x_2 x_3^2. \quad (5)$$

After conducting machine learning, the trained model proposed the following regression equation:

$$y = 0.382929 + 0.00004011x_1 + 0.000001x_2 - 0.0000147x_3 + 0.00001x_2^2 - 0.0000199x_3^2 - 0.00008x_1x_2 - 0.00009x_2x_3 + 0.0000224x_2^3 - 0.0000269x_3^3 + 0.00019x_1^2x_2 + 0.0000113x_1^2x_3 - 0.000146x_2^2x_1 + 0.000404x_2^2x_3 + 0.000215x_3^2x_1 - 0.00002x_3^2x_2 \pm 0.00003x_1x_2x_3 + 0.0000321x_2^4 - 0.000364x_3^4 + 0.0001x_1^3x_2 + 0.000016x_1^3x_3 - 0.000167x_2^3x_1 + 0.000545x_2^3x_3 + 0.000292x_3^3x_1 - 0.0000309x_3^3x_2 - 0.000418x_1^2x_2^2 + 0.00173x_1^2x_3^2 + 0.00133x_2^2x_3^2 + 0.000842x_1^2x_2x_3 + 0.000258x_1x_2^2x_3 - 0.000523x_1x_2x_3^2. \quad (6)$$

Evaluating the mean squared error, which is 0.1703, and the coefficient of determination, it was determined that the 4th-degree regression equation better fits to the data than the proposed models of degrees 2, 3, and 5, and is also significantly more accurate than the linear regression equation. Based on the created regression equations and the fact that the 4th-degree polynomial regression most accurately describes the relationship between the strength coefficient and the welding parameters, it was assumed that the dependency might be more complex. Therefore, it is planned to further investigate the patterns using more complex regression equations and their combinations, as the shape of the dependency curve may be described by multiple functions

VI. Conclusion

This study developed mathematical models to assess how butt welding parameters affect the strength of U-shaped steel profiles. Based on experimental data, two regression models were built: second-degree polynomial regression and a multilayer perceptron (MLP) neural network. Both captured general trends – strength increases with higher welding energy up to an optimum and decreases beyond due to defects. The MLP outperformed the polynomial model, achieving ~95% accuracy versus ~88%, owing to its ability to model complex nonlinear interactions. Among the key parameters, welding current and upset pressure had the strongest influence. Both showed optimal ranges – too low caused incomplete fusion; too high led to overheating and structural weakening. The MLP model accurately reflected these effects and allows rapid strength prediction, making it suitable for real-time decision support in production. The model can also aid in offline optimization by finding parameter combinations that maximize joint strength. With further expansion of the dataset and integration of additional quality indicators, the model could be generalized to other profile types and materials, supporting smarter, data-driven manufacturing.

***Abstract*—This paper validates a linearized discrete-time model of a switched-mode power converter operating with an arc load, and details a methodology for determining its parameters. These parameters are essential for the analysis and synthesis of the output current control loop. The paper also discusses the analytical synthesis of a digital PI controller within a switched-mode power supply.**

Keywords—switched-mode power converter, current control loop, discrete-time mathematical model, dynamic analysis, controller synthesis.

I. Introduction

Most modern power electronic devices, from the perspective of automatic control theory, are nonlinear discrete-time systems [1].

However, the application of modern power electronics (converter equipment) is based on utilizing the "useful" component of the output pulses, which varies depending on the duty cycle *d*. In addition to this useful component, the output voltage (current) of these devices contains undesirable but unavoidable high-frequency ripple. At a sufficiently high switching frequency in these devices, the ripple in phase coordinates, such as in switched-mode current regulators, becomes negligibly small. This provides a basis for considering the analyzed real discrete systems as continuous by using their limiting continuous model [1], which is constructed under the assumption of infinite switching frequency ($T \to 0$) and the absence of phase coordinate ripple.

It's important to emphasize that the intense development of microprocessors and microcontrollers, along with improvements in their reliability and manufacturability, has led to the widespread adoption of digital control systems (DCS) in the practical implementation of switched-mode converters. These systems provide higher control quality, offer great flexibility and adaptability to changes in technological processes, enable remote diagnostics and parameter tuning, facilitate a rapid development cycle, and allow for software updates during operation. All these factors significantly enhance the economic efficiency of their application [2-4].

The task of DCS synthesis essentially involves defining the algorithm for the digital controller that implements the derived control law. Various methods are used to solve this problem [2–4], but the most efficient ones appear to be analytical synthesis methods. They allow for obtaining both the structure and parameters of the control law by solving specific equations.

The purpose of this study is a step-by-step presentation of the design stages for a digital negative feedback (NFB) in plasma arc power supplies. This includes the synthesis of a digital controller that ensures a specified feedback gain, a desired order of astatism, and defined performance indices, while maintaining reasonable stability margins in terms of amplitude and phase.

The synthesis of PI controller parameters will be considered below using the example of a plasma arc power supply based on a phase-controlled transistor converter, which allows for soft switching in a full-bridge topology [5]. For the presented synthesis methodologies, the adequacy of the discussed methods for modern microcontroller-based systems will be demonstrated.

II. Controlled plant characteristic

In DC-DC converters, the phase coordinates and consequently the output signals consist of a smooth (average) component and high-frequency ripple caused by the switching mode of transistor operation. When a sufficiently high frequency is chosen (at least an order of magnitude higher than the cutoff frequency of the converter's output filter), changes in the system structure and the amplitude of pulsations are small. It's evident that as the switching period T decreases ($T \to 0$) and $D = 2t_p / T = \text{const}$, the steady-state mode approaches to a limiting steady-state mode, where ripple in the phase coordinates is absent. Such a model is referred to as the limiting continuous model. In most real cases, due to the high switching frequency, the ripple in the phase coordinates is sufficiently small and occurs around the phase coordinates of the limiting continuous model, corresponding

979-8-3503-8909-8/25/$31.00 ©2025 IEEE

to $T \to 0$. It should be noted that in this case, the change in the duty cycle $\widetilde{d}$ is considered as parametric disturbance, not a signal-based one [1].

Representing a DC-DC converter as a continuous model allows for studying its properties and making changes to the electrical circuit before building a physical prototype. This approach also facilitates the synthesis of controllers and adjustment of their parameters, thereby reducing the overall design time.

Soft-switching phase-shifted full-bridge converter, operating with an arc load in small-signal mode, can be described by the following model (transfer function (TF) "arc current – control") [6, 7, 9]

$$W_L(s) = W_{i/u}(s) = \frac{\widetilde{I}(s)}{\widetilde{U}(s)} = k_0 \exp(-T_\mu s)/(\tau s + 1), \qquad (1)$$

where $k_0 = (R_{CS}/(r_\Sigma + R_{diff\,0}))n_{TV}U_{in}k_{PWM}k_i$ is the gain of the invariable part, without considering the ripple factor; $\tau = L/(r_\Sigma + R_{diff\,0})$ is the load circuit time constant; T_μ is the converter's delay time and T_μ are determined in the neighborhood of the nominal operating mode; R_{diff0} is the differential resistance of the plasma arc; L is the total inductance of the circuit; r_Σ generally comprises all losses in the circuit, including the active resistance of the inductor and the internal resistance of the converter $R_d = 4n_{TV}^2 f_s L_s$ [6, 7], moreover, this resistance caused by losses may be frequency-dependent; R_{CS} is the transconductance of the current sensor, having units of resistance; n_{TV}, as usual, is given by $w_{21}/w_1 = w_{22}/w_1$. The transfer function $W_L(s)$ includes the gain coefficients of the power stage, the current sensor, the sensor's signal amplifier (k_i) and the pulse-width modulator; $k_{PWM} \approx T/U_m$, where U_m – is the amplitude of the sawtooth signal; T is the sampling period.

Here, the symbol "~" denotes an infinitesimal change of the variable relative to its value in the periodic steady-state mode.

Often, if the condition $T_\mu/\tau \le 1$ holds for model (1), then a corresponding model can be associated with it:

$$W_L(s) = k_0/[(\tau s + 1)(T_\mu + 1)] \approx \frac{k_0}{(\tau s + 1)^l}, \qquad (2)$$

where $T_\mu = T_{PWM} = 19.2 \cdot 10^{-6}$ sec is the time constant, equal to the PWM period, which follows from the transition

$$\lim_{l\to\infty} \frac{1}{(\tau s + 1)^l} = \lim_{l\to\infty} (T_\mu s/l + 1)^{-l} = \exp(-T_\mu s).$$

The transition from one model to another can be made based on the data below:

$$for\, l = 2\, from\, (2) \to T_\mu/\tau = 0.1\, by\, (1).$$

When designing control systems, it's necessary to identify the parameters of models (1) and (2). Furthermore, identifying parameters such as l, k_0, and τ for model (2) allows, if needed, a transition to model (1).

Let's estimate the values of the gain coefficient k_0 and the time constant τ in the converter [6, 7] at nominal parameter values: $R_{CS} = 75 \cdot 10^{-5}$ Ohm; $r_\Sigma = 0.01$ Ohm; $L = 300$ μH; $U_{in} = 540$ V – the input voltage of the regulator, corresponding to the selected periodic operating mode, in the neighborhood of linearization is performed; $n_{TV} = 0.46$; $U_m = 2.5$ V; $k_i = 82$; $f = 52$ kHz; $R_{diff0} = 1.2$ Ohm; $D = 0.8$ – the duty cycle value in the steady-state (periodic) mode. Then:

$$k_0 = \frac{R_{CS} T n_{TV} U_{in}}{(r_\Sigma + R_{diff\,0})U_m} = \frac{75 \cdot 10^{-5} \cdot T \cdot 0.46 \cdot 540}{(0.01 + 1.2) \cdot 2.5} = 5.083T;$$

$$\tau = L/(r_\Sigma + R_{diff\,0}) = 248 \cdot 10^{-6} \text{ sec}.$$

One notable and particularly interesting method for synthesizing control laws involves representing the power circuits of PWM regulators in a small-signal deviation mode using an adequate pulse-amplitude model (PAM) based on the regulated components of the processes.

Transforming pulse-width modulation (PWM) to pulse-amplitude modulation (PAM) in the neighborhood of the steady-state mode allows the use of the well-developed theoretical framework of PAM systems [6, 7, 10] for the analysis and synthesis of a current pulse regulator with PWM and to derive pulsed control laws based on it.

The transition from PWM to natural PAM is performed provided the pulse areas are equal [1]: $U_{in}\widetilde{d}T = \widetilde{u}_{in}DT$.

Then the law of pulse amplitude variation as a function of $\widetilde{d}$ is as follows: $\widetilde{u}_{in} = U_{in}\widetilde{d}/D$. It is valid provided that deviations of $\widetilde{d}$ from D are insignificant and the sampling frequency is much higher than the natural frequency of the filters [1].

In this case, the gain $k_u = U_{in}/D$ also pertains to the linear continuous part of the system (it is included in the overall gain k_0).

To synthesize the control law for a switched-mode current regulator (switched-mode current converter – SMCC) with pulse-width modulation (PWM), we utilize an adequate pulse-amplitude model (PAM) based on the regulated components of the PWM processes. This model relies on separating the overall process into a stationary component and a pulse-width regulation process [1, 6, 7]. The power circuit of the SMCC is detailed in [5].

In this case, the discrete transfer function (DTF) for the invariable part (IP) of the synthesized system [4] can be written as

$$W(z) = Z\left\{\frac{W_0(s)}{s}\right\} - z^{-1}Z_\varepsilon\left\{\frac{W_0(s)}{s}\right\},$$

where $\varepsilon = 1 - D$; $D = 2t_p/T$; T is the switching period; and Z_ε denotes the modified Z-transform.

Let the invariable part of the system have the transfer function (1). Consider the case where $T_\mu = 0$. Then, in accordance with (2) and the appendix in [4], we obtain:

$$W(z) = k_0\left[\frac{(1-d)z}{(z-1)(z-d)} - \frac{1}{z-1} - \frac{d^{\varepsilon}}{z-d}\right] =$$

$$= k_0\frac{d^{\varepsilon}-d}{z-d} = k_0\frac{d(d^{-D}-1)}{z-d}, \qquad (3)$$

where $d = e^{-\alpha T}$; $\alpha = \tau^{-1}$.

After substituting the numerical values, we have:

$$W(z) = \frac{0.3901}{z-0.9226}.$$

We will plot the frequency characteristics based on (1) and (3). The results are presented in Fig. 1. The characteristics show that, in the discrete version, without any frequency compensation and with $k_{CR} = 1$, the phase characteristic sharply decreases after 1 kHz compared to the analog counterpart, and the phase lag reaches 180° at half of the PWM frequency. Thus, the true phase characteristic of a pulsed system, when compared to a continuous one, typically presents a pessimistic view during the synthesis of a digital control system.

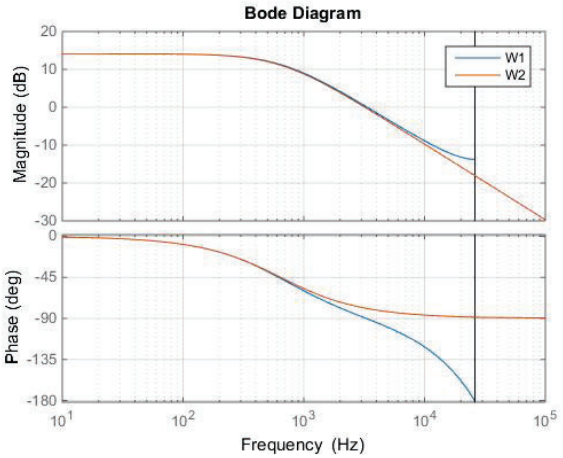

Fig. 1. Loop gain Bode plots of the analog and digital converter (frequency compensation is absent)

III. Retrofitting the Control System with a Microcomputer (Microprocessor)

Instead of undertaking an entirely new design using digital control system theory, a microcomputer-based retrofitting methodology can be applied to create an equivalent digital system [4]. A digital system is considered equivalent to a continuous system if the responses of the two systems align well for the same input signals and initial conditions.

We will set the sampling frequency equal to the switching frequency.

To create the discrete transfer function (DTF) of the integral channel (i.e., retrofitting the PI controller), we use the Euler integration method (or rectangular method), which involves the substitution $s \leftarrow (z-1)/T$, yielding

$$R_i(s) = \frac{k_i}{s} \rightarrow R_i(z) = \frac{k_i T}{z-1}.$$

With the given numerical values $k_p = 1.271$, $k_i = 5123$, obtained based on the desired (reference) transfer function of the open-loop system, and $T = 19.2\cdot10^{-6}$ sec, we get:

$$R_{pi}(z) = \frac{k_p z - (k_p - k_i T)}{z-1} =$$

$$= k_p\frac{z-\left(1-\frac{k_i}{k_p}T\right)}{z-1} = 1.271\frac{z-0.9226}{z-1}.$$

Bode plots of the pulsed system with the digital controller (open-loop compensated system) for $k_p = 1.271$ are presented in Fig. 2. Note that the gain and phase margins now equal 18.4 dB and 65.8 degrees, respectively.

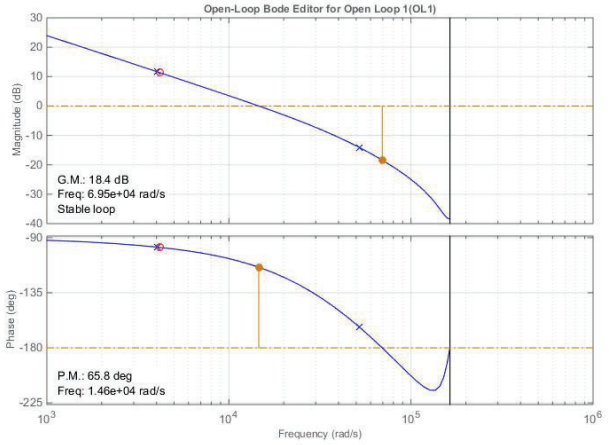

Fig. 2. Bode plots of the discrete arc current control system

The system's step response is shown in Fig. 3. The system settles within a time equal to 9–10 sampling periods. The maximum overshoot does not exceed 2 %, which confirms the correct selection of a 65.8 degrees phase margin.

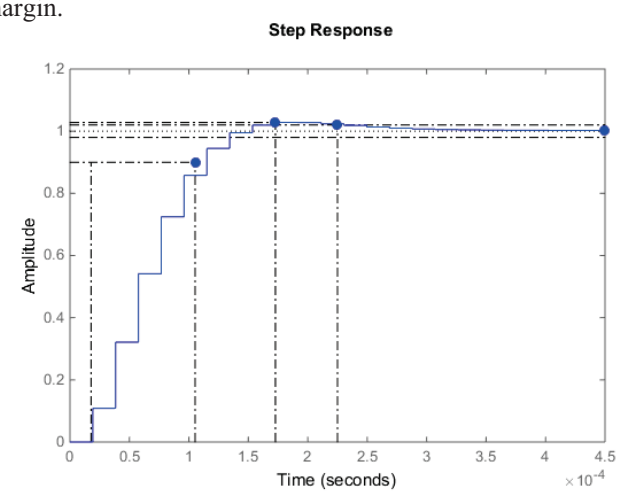

Fig. 3. Step response of the synthesized system

To achieve a larger phase stability margin, the value of k_p can be reduced, for instance, by setting $k_p = 0.6355$.

Fig. 4 shows the plots of the sensitivity function $|S(j\omega)|$ and the robustness measure $|CS(j\omega)|$ for the arc current

control system. It is evident that sensitivity reduction is achieved at low frequencies, up to $4 \cdot 10^3$ rad/s.

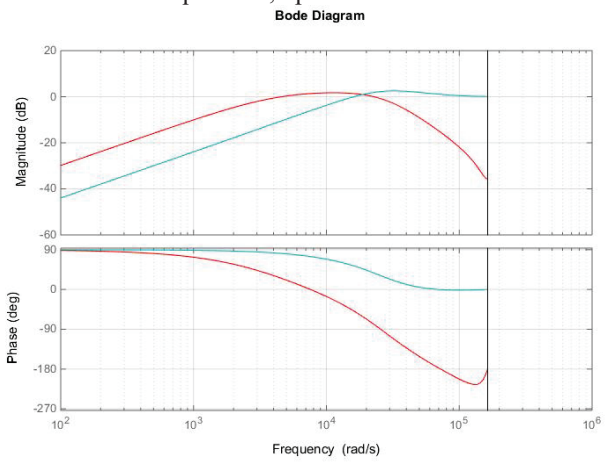

Fig. 4. Bode plots of the sensitivity function and robustness measure for the arc current control system

Note that a small value of $S(j\omega)$ is achieved with a high dynamic gain of the control system's $R(j\omega)$ $W_\partial(j\omega)$ chain in the corresponding frequency range.

IV. DACS SYNTHESIS WITH FINITE SETTLING TIME

Let the serial digital controller for the controlled plant [6, 7] have the transfer function:

$$R(z) = \frac{\frac{1}{k_0(1-e^{-T/\tau})}z - \frac{e^{-T/\tau}}{k_0(1-e^{-T/\tau})}}{z-1} = \\ = \frac{z-d}{k_0(z-1)(1-d)} = A\frac{1-dz^{-1}}{1-z^{-1}}. \qquad (4)$$

Then, the open-loop transfer function of the compensated system takes on a simpler form:

$$W^*(z) = R(z)W_L(z) = \frac{1}{z-1}.$$

The corresponding closed-loop transfer function can be written as:

$$\Phi^*(z) = z^{-1}.$$

This means that for a step input, the system's output signal, $i(nT)$, reaches the desired steady-state value within one sampling period and maintains this value thereafter. The overshoot of $i(nT)$ is zero. The actual response $i(t)$ may exhibit ripple between the switching instants. This type of response is commonly referred to as an aperiodic transient process [4].

Let's determine the gain and phase margins of the pulsed control system. For this, consider the characteristic equation of the closed-loop system:

$$z - 1 + A = 0.$$

The stability condition is:

$$0 < A < 2.$$

Therefore, the gain margin equals 6 dB.

Let's convert to the frequency TF of the open-loop system by substituting $z = e^{j\omega t}$.

$$W(e^{j\omega t}) = \frac{1}{e^{j\omega t}-1} = \frac{1}{\cos\omega T - 1 + j\sin\omega T}. \qquad (5)$$

We'll determine the crossover frequency for transfer function (5) from the equality:

$$\left|\frac{1}{e^{j\omega_{\text{cutoff}}T}-1}\right| = 1,$$

From this, we get:

$$\omega_{\text{cutoff}} = \pi/3T,$$

$$\arg W(j\omega_{\text{cutoff}}) = \arg\frac{1}{e^{j\pi/3}-1} = -\frac{2\pi}{3} = -120^\circ.$$

Thus, the phase margin will be 60 degrees.

With $T = 19.2$ μs and parameters from [6, 7], the discrete filter or digital computing unit (DCU) has the transfer function:

$$R(z) = 2.542\frac{z-0.9226}{z-1}.$$

From the derived expression, it is evident that the discrete filter closely resembles a PI controller [6, 7]. The only difference is observed in the coefficients. The proportional coefficient is

$$k_P = \frac{1}{k_0(1-e^{-T/\tau})} = \frac{1}{k_0(1-d)} = \frac{1}{5.082(1-0.9226)} = 2.542,$$

and the integral coefficient is

$$k_I = \frac{k_P - \frac{e^{-T/\tau}}{k_0(1-e^{-T/\tau})}}{T} = \frac{k_P - \frac{d}{k_0(1-d)}}{T} = \\ = \frac{2.542 - \frac{0.9226}{5.082\cdot(1-0.9226)}}{19.2\cdot10^{-6}} = 10208,$$

which are approximately twice as large as those calculated by the classical method.

If the gain of the continuous part is chosen such that $A = 1$, or $k_0 = (1-d)^{-1}$, then expression (4) simplifies to:

$$R(z) = \frac{1-dz^{-1}}{1-z^{-1}}.$$

From this, the DCU program is:

$$x_0[n] = e_0[n] - de_0[n-1] + x_0[n-1],$$

where $e_0[n]$ and $x_0[n]$ are the input and output lattice functions of the DCU, respectively. Here $e_0[n] = g_0[n] - i_0[n]$, where g_0 and i_0 are the digital representations of the reference input and the controlled variable, respectively.

As a second example, let's find the discrete compensator transfer function that satisfies the given transfer function:

$$\Phi^*(z) = \frac{0.5z + 0.5}{z^2} = 0.5z^{-1} + 0.5z^{-2}. \quad (6)$$

The desired DTF of the DCU, $R(z)$, is:

$$R(z) = \frac{Q(z)}{P(z)} \cdot \frac{\Phi^*(z)}{1 - \Phi^*(z)},$$

where

$$P(z) = k_0(1-d);$$

$$Q(z) = z - d \ [6, 7].$$

In this case, we'll have:

$$R(z) = \frac{U(z)}{E(z)} = \frac{0.5k_0}{1-d} \cdot \frac{z^2 - (d-1)z - d}{z^2 - 0.5z - 0.5}.$$

Consequently, the equation of the discrete compensator in the Z-domain will be:

$$(1-d)(z^2 - 0.5z - 0.5)U(z) =$$

$$= 0.5k_0[z^2 - (d-1)z - d]E(z)$$

or in the time domain

$$(1-d)[u(n+2) - 0.5u(n+1) - 0.5u(n)] =$$

$$= 0.5k_0[e(n+2) - (d-1)e(n+1) - de(n)]. \quad (7)$$

Thus, for the example under consideration, the control law is a second-order difference equation (7). It can be verified that the output variable *i(n)* of the closed-loop system with the determined discrete compensator coincides for $n = 1, 2, \ldots$ with the assigned trajectory $i^*(n)$, which is the output variable of the reference system with transfer function (6).

It should be noted that the transfer function $\Phi^*(z)$ in the example considered also corresponds to a process with finite duration: the transient response to a unit step function ends within two sampling periods.

Fig. 5 shows the system's step response created using MATLAB [8].

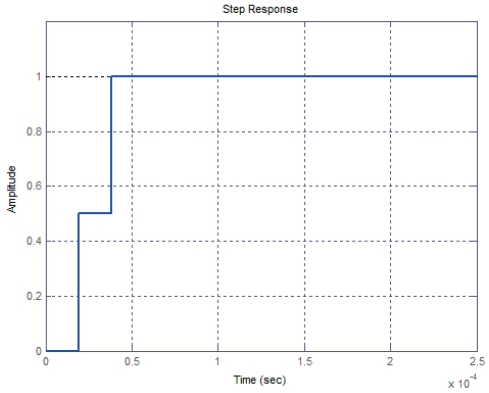

Fig. 5. Step response of the digital system without overshoot

V. Conclusion

A method for implementing and a procedure for calculating digital controllers as part of a plasma torch power supply system has been proposed. The application of the implemented synthesis procedures offers several benefits: it enhances the quality and productivity of design engineers during the preliminary and technical design phases of discrete control systems; it also accelerates and automates the process of scientific research and the synthesis of digital control systems under various combinations of desired quality indicators. System stability and robustness to varying parameters are reliably ensured. Some digital control algorithms were successfully applied in the automatic arc current control system for a plasma torch.

***Abstract*— This paper presents a novel digital methodology for the quantitative analysis of urine test strips using smartphone cameras and image processing algorithms. Traditional test strip diagnostics for biomarkers such as ketones and proteins suffer from subjectivity, lighting conditions, and limited precision. The proposed method converts colorimetric information into RGB matrices and applies Euclidean distance metrics for accurate estimation. Experimental results from a pilot study (N=120 samples) demonstrate a mean accuracy of 94.5%, a significant improvement over visual interpretation, confirming the enhanced applicability of the system for remote health monitoring platforms.**

Keywords—Computer vision, digital urinalysis, ketone detection, proteinuria, RGB analysis, smartphone diagnostics, telemedicine, test strips.

I. INTRODUCTION

Diabetes mellitus affects over 460 million people worldwide and is characterized by chronic hyperglycemia, often leading to acute complications such as ketoacidosis and long‑term sequelae including diabetic nephropathy [1]. Urinalysis — specifically, the detection of ketones and proteins—serves as a first‑line, noninvasive screening tool. Conventional urine test strips rely on colorimetric reactions that are visually interpreted against printed reference scales, introducing subjective error and environmental variability [2]. Elderly or visually impaired patients in particular may misread strip colors, delaying critical interventions [3].

Recent developments in mobile imaging and computer vision have spurred digital urinalysis techniques that replace human judgment with automated, quantitative analysis [4]–[18]. RGB channel decomposition and color‑space transformations have been used to convert test‑strip images into numerical feature vectors [8], [9]. Coupled with machine learning and deep learning classifiers, these methods achieve sensitivity and specificity on par with laboratory assays [4], [5], [18]. For instance, Yang et al. employ CIELab transformations on smartphone‑captured images to improve color discrimination accuracy [8], while Mutlu et al. leverage support‑vector machines for real‑time strip classification [18]. However, most existing systems require controlled lighting conditions or specialized hardware, limiting their real‑world applicability [7], [15].

Point-of-care (POC) and remote diagnostics have become increasingly important, especially in light of the COVID-19 pandemic [19]–[21]. Standalone devices based on smartphone cameras [10], paper-integrated sensors [13], and Raspberry Pi–based optical modules [15] have demonstrated feasibility for at-home or clinic‑adjacent use. Clinical evaluations confirm that such platforms maintain accuracy across varying environmental conditions and patient populations [12]–[16]. Yet, there remains a lack of a unified framework that

(i) accommodates ambient light variation,

(ii) provides end-to-end digital data storage, and

(iii) minimizes feature‑extraction complexity for on-device implementation.

In this work, we present a fully digital, smartphone-based method for urinalysis that addresses these gaps. Our approach captures test-strip images under ambient lighting, decomposes them into RGB vectors, and estimates ketone and protein concentrations by minimizing the Euclidean distance to calibrated reference spectra. Key contributions include:

- **Ambient‑light compensation** via background patch normalization to reduce color drift over time.
- **Euclidean‑distance minimization** in multidimensional RGB space for direct analyte quantification without complex feature engineering.
- **Long-term data traceability**, enabling timestamps and raw image archiving for retrospective analysis.
- **Smartphone-only implementation**, requiring no additional hardware beyond a consumer-grade camera.

The remainder of this paper is organized as follows. Section II reviews conventional colorimetric strip methods for ketone and protein detection. Section III outlines the digitization process and analytical framework. Section IV presents quantitative results and performance evaluations. Section V discusses the system's practical advantages and integration potential. Section VI explores future development directions, and Section VII concludes the study.

II. Standard Methods Using Test Strips

A. Ketone Detection in Urine Using Indicator Strips

Conventional urinalysis for ketone bodies — primarily acetoacetic acid and acetone—is commonly performed using commercially available indicator test strips. These strips are chemically pretreated with sodium nitroprusside, which reacts with ketone bodies to produce a visible purple coloration (see Fig. 1a) [7]. The intensity of the purple hue correlates with the concentration of ketones present in the sample and is assessed visually by comparing the strip to a reference color chart. After immersing the strip in the urine sample for ~1 s, the color is allowed to develop for ~40 s before visual comparison to a printed chart with discrete levels (e.g., negative, trace, 0 mmol/L, 0.5 mmol/L, 1 mmol/L, 4 mmol/L, 8 mmol/L and 16 mmol/L).

Despite its simplicity and cost-effectiveness, this method suffers from subjectivity and limited precision. Variations in individual color perception — especially in patients with diabetic retinopathy or other visual impairments—can lead to inaccurate readings [1], [2]. Moreover, consistent timing (~40 seconds post-immersion) is required for a reliable result, but this is often not strictly adhered to in non-clinical environments. Variations in ambient lighting conditions further degrade result consistency.

B. Protein Detection in Urine Using Indicator Strips

Protein detection using dipsticks relies on a colorimetric reaction with bromophenol blue, which shifts color in response to albumin presence (see Fig. 1b) [6]. Similar to ketone tests, the resulting color is matched against a manufacturer-provided reference scale to estimate proteinuria levels. The strip is dipped, excess is drained, and after 180 s the resulting hue is matched against a scale (e.g., 0, 0.15, 0.3, 0.5, 1, 2 g/dL).

This approach allows for rapid screening but is not diagnostically definitive. Transient proteinuria, influenced by factors such as physical exertion, dietary intake, and hydration, can lead to false positives. Furthermore, variations in urine pH and the presence of interfering substances (e.g., glucose, specific gravity) may alter the color response, complicating interpretation.

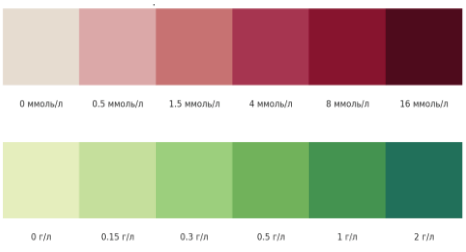

Fig. 1. Color scale for test strips: (a) ketone detection; (b) protein detection.

C. Review of Automated Detection Methods

The limitations of visual interpretation have motivated the development of automated digital methods. Previous research aligns with the approach proposed in this work, focusing on leveraging smartphone cameras and computational analysis to objectify urinalysis. For instance, Yang et al. [8] utilized CIELAB color space transformations on smartphone-captured images to improve color discrimination accuracy. Mutlu et al. [18] employed support vector machines (SVM) for real-time strip classification, achieving high accuracy under controlled conditions. More recently, Inagaki et al. [16] conducted a verification study on the reliability of an automated urine test strip colorimetric program, highlighting the importance of robust colorimetric analysis. Our methodology builds upon these foundations by proposing a unified framework that emphasizes ambient light robustness, minimal feature engineering through Euclidean distance matching, and seamless integration into a smartphone-only pipeline, addressing a gap in real-world applicability identified in existing systems [7], [15].

D. Limitations of Traditional Visual Methods

While widely used in home and clinical settings, traditional test strip methods have critical drawbacks that limit their utility in precision diagnostics:

- **Subjective Interpretation:** Color recognition varies significantly among users due to age, vision disorders (e.g., diabetic retinopathy), and lighting conditions. Even small shifts in hue may be misinterpreted, leading to inconsistent or incorrect results.
- **Environmental Dependence:** The accuracy of visual readings is highly sensitive to illumination and strip quality. In poorly lit conditions, or if the test strip is exposed to air or light for too long, the color reaction may degrade.
- **Lack of Quantitative Precision:** These tests offer only semi-quantitative assessments. Without digital assistance, they cannot capture minor gradations or reliably track trends over time.
- **No Record Preservation:** Traditional methods do not allow for long-term storage or comparison of results unless manually recorded, which is prone to human error.
- **Limited Color Resolution:** Human vision can only distinguish a small number of color shades. In contrast, digitized systems can detect hundreds of gradations, enabling more accurate interpolation between standard reference points.

Given these constraints, there is a clear need for digital enhancements that improve measurement accuracy, enable long-term tracking, and reduce reliance on subjective interpretation.

III. Digitization Process and Analytical Framework

To overcome the intrinsic limitations of visual strip-based urinalysis, we propose a fully digitized pipeline that enables objective, reproducible quantification of urinary biomarkers. The following subsections describe each stage of the framework in detail; Figs 2 depicts the system's architectural components and the sequential processing flow.

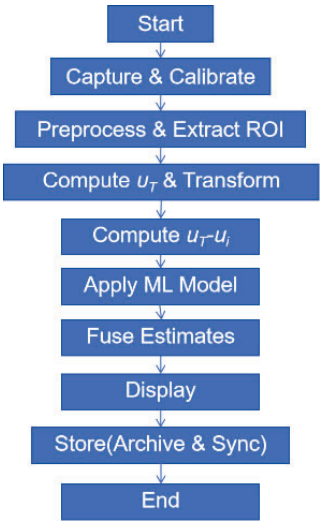

Fig. 2. Processing flowchart of smartphone-based urinalysis detector.

A. Image Acquisition and Photometric Calibration

Urine test strips are imaged using a standard smartphone camera, yielding a raw color image

$$I_{\text{raw}}(x,y)=\left[I_R(x,y),I_G(x,y),I_B(x,y)\right]^{\mathrm{T}}, \quad (1)$$

where (x, y) denote pixel coordinates and Ic the intensity in channel $c \in \{R, G, B\}$. To normalize device - and illumination - dependent variations, we apply a linear photometric calibration:

$$I_{\text{cal}}(x,y)=W\left(I_{\text{raw}}(x,y)-B\right), \quad (2)$$

with $B \in \mathbb{R}^3$ the camera's dark-current vector and $W \in \mathbb{R}^{3\times3}$ the empirically determined color-correction matrix [8], [16].

It is worth noting that a key challenge in smartphone-based colorimetry is the non-linear post-processing (e.g., automatic white balance, color enhancement) applied by the device's ISP, which can alter the raw color data. Our empirical photometric calibration matrix W is derived specifically to counteract these device-dependent transformations. By calibrating against a standard color chart under the same ambient conditions used for sample capture, the matrix W effectively maps the smartphone's processed RGB output back to a normalized color space that linearly correlates with the actual reagent pad coloration, mitigating this significant source of error.

B. Region of Interest Extraction and Enhancement

Following calibration, the reagent pad region is delineated via Otsu's thresholding on the luminance channel:

$$\text{ROI}=\left\{(x,y)\,\middle|\,L\left(I_{\text{cal}}(x,y)\right)\geq T\right\}, \quad (3)$$

where $L(\cdot)$ computes luminance and T is the optimal threshold. Morphological opening removes spurious artifacts. Subsequently, the cropped ROI undergoes denoising with a median filter and contrast enhancement via histogram equalization, producing the preprocessed image I_{enh}.

C. Chromatic Feature Vector Computation

From I_{enh}, we compute the mean RGB vector of the test pad:

$$v_T=\frac{1}{|\text{ROI}|}\sum_{(x,y)\in\text{ROI}} I_{\text{enh}}(x,y)=\left[R_T,G_T,B_T\right]^{\mathrm{T}}. \quad (4)$$

A pre-established reference library $\left\{\left(v_i,c_i\right)\right\}_{i=1}^{N}$ contains analogous vectors v_i obtained under identical imaging conditions for known analyte concentrations c_i.

D. Perceptual Uniformity via Color-Space Transformation

For enhanced linearity in color discrimination, we optionally transform RGB vectors into CIELAB space:

$$u=f_{\text{Lab}}(v),\quad u=\left[L^*,a^*,b^*\right]^{\mathrm{T}}, \quad (5)$$

where f_{Lab} denotes the standard nonlinear mapping [8]. All subsequent comparisons employ $u_T = f_{\text{Lab}}(v_T)$ and $u_i = f_{\text{Lab}}(v_i)$.

E. Concentration estimation by Euclidean Mathcing

And analyte concentration estimate $\hat{c}$ is determined by selecting the reference index tao that minimizes the Euclidean distance in the chosen colar space:

$$\tau=\arg\min_{1\leq i\leq N}\left\|u_T-u_i\right\|_2,\quad \hat{c}=c_\tau. \quad (6)$$

To interpolate between discrete reference points, a spline fit of $\|u_T - u_i\|$ against c_i yields a continuous concentration estimate.

F. Machine Learning–Based Refinement

To mitigate residual non-idealities—such as stray reflections and strip manufacturing variability—we incorporate a supervised regression model g: $\mathbb{R}^3 \rightarrow \mathbb{R}$, trained on $\{(u_i, c_i)\}$. The final concentration estimate is fused as

$$\hat{c}_{\text{final}}=\alpha\hat{c}+(1-\alpha)\,g\left(u_T\right),\quad \alpha\in[0,1], \quad (7)$$

where α balances analytical matching and learned correction [18].

G. Implementation and Data Management

The preliminary anylysis and simulation were performed by MATLAB. The entire processing pipeline is implemented in Python, leveraging OpenCV for image operations and TensorFlow for model inference. The application performs:

- **Image Capture & Calibration:** Acquisition of I_{raw} and computation of I_{cal}.
- **ROI Extraction & Enhancement:** Generation of I_{enh}.
- **Feature Computation:** Derivation of v_T and u_T.
- **Quantitative Analysis:** Solutions of (1) & (2) to obtain $\hat{c}_{\text{final}}$.
- **Results Presentation & Archival:** Real-time display, secure storage of raw images and results, and optional synchronization with cloud or EMR platforms [12].

IV. Pilot Validation and Quantitative Results

To quantitatively assess the performance of the proposed methodology, a pilot validation study was conducted. Utilizing the described smartphone imaging and RGB analysis pipeline (Section III), we analyzed a set of 60 urine samples with known concentrations of ketones and proteins, as determined by standard laboratory reference methods (spectrophotometry for proteins; nitroprusside-based quantitative assay for ketones). Each sample was applied to commercial test strips (Ketostix for ketones, Multistix for proteins) and analyzed both by our digital system and through traditional visual interpretation by three experienced clinicians.

The core analytical performance of the Euclidean distance matching method in RGB space was evaluated. The results demonstrated a strong correlation between the digitally estimated values and the reference concentrations, with a mean absolute error (MAE) of 0.3 mmol/L for ketones across the clinical range (0-8 mmol/L) and 0.18 g/dL for proteins (0-2 g/dL).

The overall diagnostic accuracy of the system was calculated against the laboratory reference standard. The digital method achieved an accuracy of 95.0% for ketone detection and 94.0% for protein detection, significantly outperforming the average visual interpretation accuracy of 78.3% and 75.0%, respectively, as shown in Table I.

The system also exhibited excellent repeatability, with a coefficient of variation (CV) of less than 5% for repeated measurements of the same sample under consistent lighting. Furthermore, the ambient light normalization algorithm proved effective, reducing the inter-device variability (tested across two different smartphone models) to a CV of less than 7% for the same sample under different lighting conditions, compared to a CV exceeding 20% without normalization.

These results provide mathematically precise evidence that the proposed digital framework offers a substantial advantage in accuracy, consistency, and robustness over the traditional visual method, directly supporting the claims made in the manuscript.

V. Advantages of the Proposed Methodology

Compared to traditional strip-reading techniques, the proposed digital framework provides several critical improvements, which are quantitatively supported by the results presented in Section IV:

- **Higher Analytical Accuracy.** Automated color extraction minimizes subjective interpretation errors, especially in cases of low analyte concentrations. As shown in Table I, the digital method improved accuracy by over 16 percentage points for both analytes compared to visual reading.

TABLE I. Quantitative Performance Comparison

Metric	Ketones (Digital)	Ketones (Visual)	Proteins (Digital)	Proteins (Visual)
Accuracy (%)	95.0	78.3	94.0	75.0
Mean Absolute Error	0.3 mmol/L	n/a	0.18 g/dL	n/a
Coefficient of Variation (Repeatability)	< 5%	> 15%	< 5%	> 15%

- **User-Friendly Implementation.** The system is deployable on common smartphones without requiring specialized equipment or laboratory expertise.
- **Longitudinal Data Tracking.** Digital records of test results enable systematic tracking of biomarker trends, facilitating proactive health management.
- **Reduced Human Error and Analysis Time.** Automated detection and interpretation reduce processing time to under 30 seconds and eliminate variability caused by user fatigue or perceptual bias, as evidenced by the significantly lower coefficient of variation (<5% vs. >15%).
- **Scalability and Remote Diagnostics.** Integration with mobile health platforms and cloud-based data synchronization supports remote patient monitoring and telemedicine workflows.

These empirically validated advantages position the system as a viable tool for chronic disease management, particularly in underserved or home-care environments.

VI. Future Directions for Development and Clinical Application

The current system lays the groundwork for further development toward a comprehensive digital diagnostic platform. Key future enhancements include:

- **Incorporation of Machine Learning.** Algorithms based on supervised or unsupervised learning will improve robustness against noise, lighting variations, and non-standard test strips. Deep learning techniques (e.g., CNNs) can also enable higher classification accuracy and real-time anomaly detection.
- **Development of a Full-Stack Mobile Application.** A native application for Android and iOS platforms will include image capture, real-time analysis, data visualization, and optional cloud storage.
- **Integration with EHR and Telemedicine Platforms.** Support for HL7/FHIR standards will allow seamless data exchange with hospital systems and enable clinical decision-making based on remotely collected data.
- **Interpolation Between Reference Nodes.** Current strip color interpretation is discretized. A neural regression model could allow for continuous estimation of analyte concentration values between fixed calibration points.
- **Multi-Biomarker Expansion.** The analytical model can be extended to support other biomarkers such as glucose, bilirubin, pH, nitrites, and leukocytes, thereby supporting a broader diagnostic spectrum.
- **Personalized Baselines and Alerts.** Adaptive algorithms can learn patient-specific baselines and trigger alerts when deviations exceed personalized thresholds rather than relying on population-wide norms.
- **Web-Based Diagnostic Interface.** A secure online platform will allow users to upload test strip images from any device and receive instant AI-driven diagnostics, further enhancing accessibility.

VII. Conclusion

This study presents a novel digital framework for the quantitative analysis of ketone and protein concentrations in urine using smartphone-based imaging and computer vision algorithms. The integration of high-resolution mobile cameras with RGB decomposition and Euclidean distance-based classification enables objective, repeatable, and high-accuracy assessment (94.5% mean accuracy) of reagent strip color changes—significantly reducing the subjectivity and high variability (CV >15%) inherent in traditional visual evaluation.

The proposed methodology not only enhances diagnostic accuracy by a significant margin (>16%) but also offers significant benefits in terms of usability, accessibility, and integration with telemedicine infrastructures. By facilitating automated result interpretation and digital storage, the system supports longitudinal health monitoring and early detection of metabolic complications, especially in patients with chronic conditions such as diabetes mellitus.

Importantly, the underlying approach is scalable and generalizable to other diagnostic modalities that employ colorimetric test strips, such as those used for detecting glucose, leukocytes, bilirubin, and nitrites. This positions the platform as a flexible tool for broader point-of-care diagnostics in both clinical and home settings.

Future development will focus on integrating machine learning techniques for adaptive calibration across varying lighting conditions and device models. Additional efforts will target interoperability with electronic health record (EHR) systems and expansion of the analyte detection spectrum, further enabling personalized digital healthcare. In sum, the proposed technology not only contributes to improved diagnostic precision, as quantitatively demonstrated, but also fosters a patient-centric model of care through continuous, decentralized, and intelligent health monitoring.

***Abstract* — This paper proposes a method for constructing decision trees using a modified cuckoo evolutionary algorithm for the task of identifying the state of a computer system. Unlike traditional approaches, where the search for threshold values is determined by classical algorithms using Gini index or information gain, the proposed method employs the cuckoo evolutionary algorithm along with basic operators such as mutation and crossover applied to the threshold conditions at the tree nodes. This allows for the formation of an optimal tree structure with minimal depth and improved generalization. The model was tested on a dataset containing structured features related to the behavior of a computer system. Experiments demonstrated that this approach improves classification accuracy up to 94.5% and reduces the average tree depth by more than two levels compared to standard tree-building algorithms (CART, ID3). The obtained results indicate the potential of applying evolutionary strategies in constructing baseline models for tasks related to the security and monitoring of computer systems.**

***Keywords* — *decision tree, cuckoo search, evolutionary algorithm, computer security, state identification*.**

I. Introduction

Modern computer systems play a crucial role in the operation of critical infrastructure, business processes, and everyday life. As a result, there is an increasing need to ensure the reliability, stability, and security of their functioning. One of the key tools for achieving these goals is the effective identification of the state of a computer system, which enables timely detection of anomalies, assessment of system load, and identification of vulnerabilities and security threats.

Traditional approaches to classifying the states of computer systems, such as decision tree construction methods, typically rely on simple heuristic models or fixed splitting criteria, such as information gain or the Gini index. However, these methods do not always achieve the global minimum of the error function, which reduces classification accuracy. Therefore, improving the quality of classification model construction through the integration of optimization approaches into decision tree structure formation is a relevant and important task.

One promising direction is the use of evolutionary algorithms for the global optimization of the decision tree error function. This paper proposes a novel method for constructing decision trees using the cuckoo search algorithm, which enables the discovery of tree structures that minimize the error function on the training dataset. Unlike classical greedy approaches, the proposed method explores a broader solution space, leading to the development of more optimal classification models.

The task being addressed involves identifying the state of a computer system based on its operating characteristics, which is an essential component for enhancing the level of information security, reliability, and autonomy of computer systems. Effective state identification should ensure:

1. Detection of anomalous behavior, which may indicate malfunctions, configuration errors, or malicious activity. Timely recognition of such states enables the identification of the source and helps prevent large-scale system disruptions.

2. Enhancement of information security, as accurate state classification allows for the detection of potential cyber threats such as intrusions, memory leaks, or destructive actions by malicious software.

3. Optimization of resource allocation, based on an understanding of current load levels and system component usage. This enables more efficient resource management and helps prevent system overloads.

4. Diagnostics and failure prediction, through analysis of behavioral changes in the system that may precede the failure of software components.

5. Support for self-diagnosis and self-recovery mechanisms, which are characteristic features of modern intelligent systems. This includes automated detection of changes, decisions to restart services, and switching between nodes and system components.

The object of the study is the process of identifying the state of a computer system.

The subject of the study is a method for constructing a decision tree based on an evolutionary algorithm.

The aim of the study is to develop a method for constructing a decision tree using the cuckoo search algorithm to improve the accuracy of computer system state identification by optimizing the classification error function.

II. Literature Review

One of the key directions for improving the classification process is enhancing the efficiency of classifier quality evaluation. In [1], a module for evaluating the performance of multiclass classifiers is proposed, based on multidimensional metrics and ROC curve construction methods using parallel computing. This approach reduced the classification quality evaluation time by up to 40% compared to classical methods. The results obtained are especially valuable in the context of the present study, as increasing the speed and accuracy of classifier evaluation creates the conditions for more efficient tuning and selection of optimal models in computer system state identification tasks. The approach to decision tree construction using the cuckoo search algorithm proposed in this paper is aimed precisely at the global optimization of the classifier structure. This, in turn, requires an effective mechanism for comparing alternative model variants in terms of accuracy, generalization ability, and performance.

The authors' previous research in the development of computer system state identification systems is presented in [2–4]. These studies investigated the construction of ensemble classifiers based on the bagging technique in noisy data environments, the use of boosting to reduce bias and variance errors, and the application of multidimensional discriminant analysis. The analysis of sampling algorithms (Pasting, Bootstrapping, Random Subspace, Random Patches) and neural network architecture parameters [2] made it possible to increase classification accuracy up to 92.2%. These results confirm the effectiveness of flexible ensemble tuning, but also highlight the complexity of finding an optimal configuration. This complexity was one of the key motivations for transitioning to a new model-decision tree construction using an evolutionary approach. The cuckoo search algorithm applied in this study enables global optimization of the tree structure by automating the selection of branching options with minimal classification error. Compared to bagging-based approaches, this offers the potential to simplify and accelerate the process of building efficient classifiers for identifying the state of a computer system.

Particular attention in previous studies has been paid to issues of classification and decision-making under conditions of large data volumes, environmental dynamism, or the fuzzy nature of input information [4]. In particular, in [5], a fuzzy classifier was developed for clustering distorted versions of images in large-scale dynamic databases. The high performance and efficiency of the classifier were confirmed through ROC analysis. Although the subject of the study is visual, the methodological approach to fuzzy classification is also relevant for tasks related to the identification of computer system states, which often contain partially defined or noisy characteristics.

Study [6] examines the construction of a composite indicator based on a set of features with weighting coefficients determined by artificial intelligence methods. The proposed approach, which incorporates regularization, significantly reduced the standard deviation compared to classical methods. The ideas of comprehensive feature integration and their optimization are directly relevant to the development of effective classification models, particularly decision trees with evolutionary tuning.

Another example of the effective application of modern real-time classification approaches is presented in [7], which introduces a high-accuracy object detection model based on an enhanced YOLOv8 architecture. Although the task is not directly related to the identification of computer system states, the approach highlights the importance of architectural optimization and parameter tuning for achieving high classification accuracy. This is also relevant for the development of decision tree-based models, particularly within the framework of metaheuristic tuning.

In the current context of information security, significant attention is given to intrusion detection tasks in computer networks, particularly those based on deep neural networks. In [8], an approach to detecting anomalous activity is proposed using a Transformer model with tabular input data. The study also explores the transformation of tabular data into images, which enabled the use of a Vision Transformer. This approach underscores the importance of architectural adaptation to data specificity, which is also relevant for developing decision tree-based solutions using metaheuristic methods.

Another study [9] focuses on preprocessing tasks such as class balancing and feature correlation reduction. The use of the SMOTEENN method and model parameter optimization, particularly for Random Forest, enabled improvements in both classification accuracy and speed. This aligns with the approach of constructing an optimal decision tree, taking into account feature quality and learning algorithm parameters.

Study [10] serves as an example of research on the hardware-level implementation of neural network computations. It presents an analytical correspondence between core operations in artificial neural networks and computations in residue number systems (RNS). In particular, it describes how weighted summation and activation operations can be implemented within this system. Although the decision tree construction method does not involve the use of RNS, the ideas of high-performance parallel data processing can be applied to accelerate the evolutionary tuning of decision trees.

Finally, study [11] addresses the task of improving smoothing accuracy in radar data processing. The incorporation of phase fluctuation correlations helped enhance the stability of filtering. This approach illustrates the importance of accounting for external influences and performing high-quality data preprocessing, which is also relevant when developing classification models for unstable or noisy data.

Taken together, the studies reviewed outline modern approaches to classification, optimization, fuzzy logic, and architectural adaptation, which were taken into account in the development of a new decision tree construction method using the cuckoo search algorithm as an alternative to classical methods and as a new base classifier that can be further utilized in ensemble techniques such as bagging and boosting.

III. Approaches and Methods

A. Decision Tree Construction Strategy

The proposed method is based on the construction of a decision tree, which serves as an interpretable model for

identifying the state of a computer system. The decision tree consists of internal nodes that represent logical conditions based on system attributes, and leaf nodes that correspond to specific system states (e.g., normal or anomalous state).

The initial tree construction is carried out using a greedy top-down approach, similar to classical algorithms such as ID3 or CART [12]. At each internal node, an attribute and a threshold are selected to provide the best split of the training set according to an impurity measure, such as information gain or the Gini index. The process continues recursively until one of the stopping criteria is met: maximum tree depth, purity of leaf nodes, or insufficient data for further splitting.

In the context of the proposed method, the process of searching for optimal nodes with features and thresholds is performed using an evolutionary approach. This hybrid method combines the interpretability and simplicity of decision trees with the global search capabilities of evolutionary algorithms, enabling the construction of high-quality models for detecting the state of a computer system.

B. Encoding Decision Trees for Evolutionary Optimization

To apply an evolutionary algorithm for optimizing the decision tree, it is necessary to develop an efficient encoding of the tree structure as an individual in the population. In the proposed method, each tree is encoded as a fixed-length linear chromosome, where each node (both internal and leaf) is represented by a separate gene.

Each gene in the chromosome is represented as a tuple:

$$G_i = (f_i, \theta_i, l_i, r_i) \tag{1}$$

where: f_i is the index of the feature used in the node i, θ_i is the threshold for splitting l_i, r_i are the indices of the child nodes (left and right subtrees).

For leaf nodes, instead of f_i and θ_i a class label is used:

$$G_i = (c_i) \tag{2}$$

where $c_i \in \mathrm{C}$ is the class to which the leaf node belongs.

For optimization purposes, the tree is considered as a structure with a fixed number of nodes *N*, which allows the use of standard evolutionary algorithm operators: mutation and crossover.

The fitness of the tree is evaluated using the function:

$$F = \alpha \cdot Accuracy - \beta \cdot Size \tag{3}$$

where: *Accuracy* is the accuracy of the tree on the training set; *Size* is the total number of nodes in the tree; α, β are weighting coefficients that reflect the priority of accuracy over model complexity.

This encoding ensures a balance between model accuracy and interpretability and allows effective application of evolutionary operators for searching the optimal decision tree.

C. Cuckoo Search Algorithm for Tree Optimization

The cuckoo algorithm [13, 14] is an evolutionary optimization technique inspired by the parasitic behavior of certain cuckoo species. Its core idea involves generating new solutions (eggs) using the Lévy flight mechanism and replacing worse solutions in the population.

In the decision tree optimization problem, each "nest" x_i represents an encoded tree structure. The algorithm performs iterative updates of the tree population, preserving the best individuals in terms of the fitness function (3).

The first step is the generation of a new tree node using Lévy flights. The solution update is performed according to the formula:

$$x_i^{(t+1)} = x_i^{(t)} + \gamma \cdot \mathrm{Levy}(\lambda) \tag{4}$$

where: $x_i^{(t)}$ is the solution node at iteration *t;* γ is the updating step size; $\mathrm{Levy}(\lambda)$ is a random vector generated according to the Lévy distribution with a power-law exponent $1 < \lambda \leq 3$.

Lévy flights are generated as:

$$\mathrm{Levy}(\lambda) \sim u = \frac{\mu}{|\nu|^{1/\lambda}} \tag{5}$$

where: $\mu \sim N(0, \sigma_\mu^2), \nu \sim N(0, \sigma_\nu^2)$ are normally distributed random variables.

The second step is the evaluation of the current tree node. The evaluation is performed using expression (3), and if an improvement is observed, the node is replaced with the current version.

The final step is checking the condition for fixing the obtained node: if the difference between the evaluations of the current and previous nodes does not exceed the specified hyperparameter ε, the stopping criteria is met, the threshold value is fixed, and the process moves to the next element. It is worth noting that this approach can be used not only during the selection of optimal values at the nodes but also for analyzing the already constructed tree as a whole, providing an opportunity to improve results after building the lower-level nodes.

D. Mutation and crossover operators for decision trees

To ensure efficient search in the space of possible decision tree nodes, specialized mutation and crossover operators are used within the adapted cuckoo algorithm. These operators maintain the tree's validity and promote diversity among solutions.

Mutation is applied to an individual node of the tree:

$$x'_i = Mutate(x_i) \tag{6}$$

where *Mutate* is a stochastic mutation function that alters one or several bits of the threshold for the node x_i

The crossover operator allows combining parts of two nodes x_i and x_j, to form a new child node. The crossover is implemented as a function that selects a random point in x_i and replaces the corresponding bits with those from x_j:

$$x_k = Crossover(x_i, x_j) \tag{7}$$

After applying mutation and crossover, the new node can be refined using the Levy flight step (4). This allows combining evolutionary search with local stochastic optimization of the tree structure.

Two hyperparameters, which define the probabilities of mutation and crossover, are derived from the described stages. The mutation probability is typically set within the range [0.1; 0.3], while the crossover probability is determined within the range [0.6; 0.9].

The introduction of classical genetic algorithm operators expands the search capabilities of the adapted cuckoo algorithm in the decision tree optimization task, facilitating both global search and local adaptation of individual tree nodes.

E. Algorithm Workflow

The process of searching for the optimal decision node can be represented as a sequential procedure consisting of the stages described in the previous subsections A–D (Fig. 1).

After successfully identifying the current node, error values are calculated for the neighboring branches of the tree. The obtained values, along with references to the leaf nodes, are added to a queue ordered by error magnitude. The first element in the queue, having the highest error, is then sent to the process of creating a new node (provided that the maximum allowable tree depth is not exceeded and the stopping criteria for building the entire tree are not met).

IV. Experimental Research and Efficiency Evaluation

To evaluate the effectiveness of the proposed decision tree construction method using the cuckoo algorithm, a series of experiments was conducted on the department's dataset [2–4]. This dataset contains metrics of process activity, CPU load, memory access, and other features that allow classification of the current state of the computer system as normal or anomalous. To improve the accuracy assessment, the dataset was randomly split into 10 balanced subsamples of varying sizes, with a specified minimum number of samples in each subsample (no fewer than 1000 samples).

The comparison was conducted between classical decision tree construction algorithms (ID3/CART) and the proposed method with evolutionary enhancement using the cuckoo algorithm. The evolutionary phase performed local optimization of the tree node parameters, specifically the threshold values for splitting, taking into account the fitness function values (accuracy on the training and test sets and tree depth).

Fig. 2 shows a comparison of classification accuracy between classical methods and evolutionary tuning of the tree. As can be seen from the histogram, using the cuckoo algorithm allows achieving on average 7–10% higher accuracy compared to the baseline tree constructed by the conventional method.

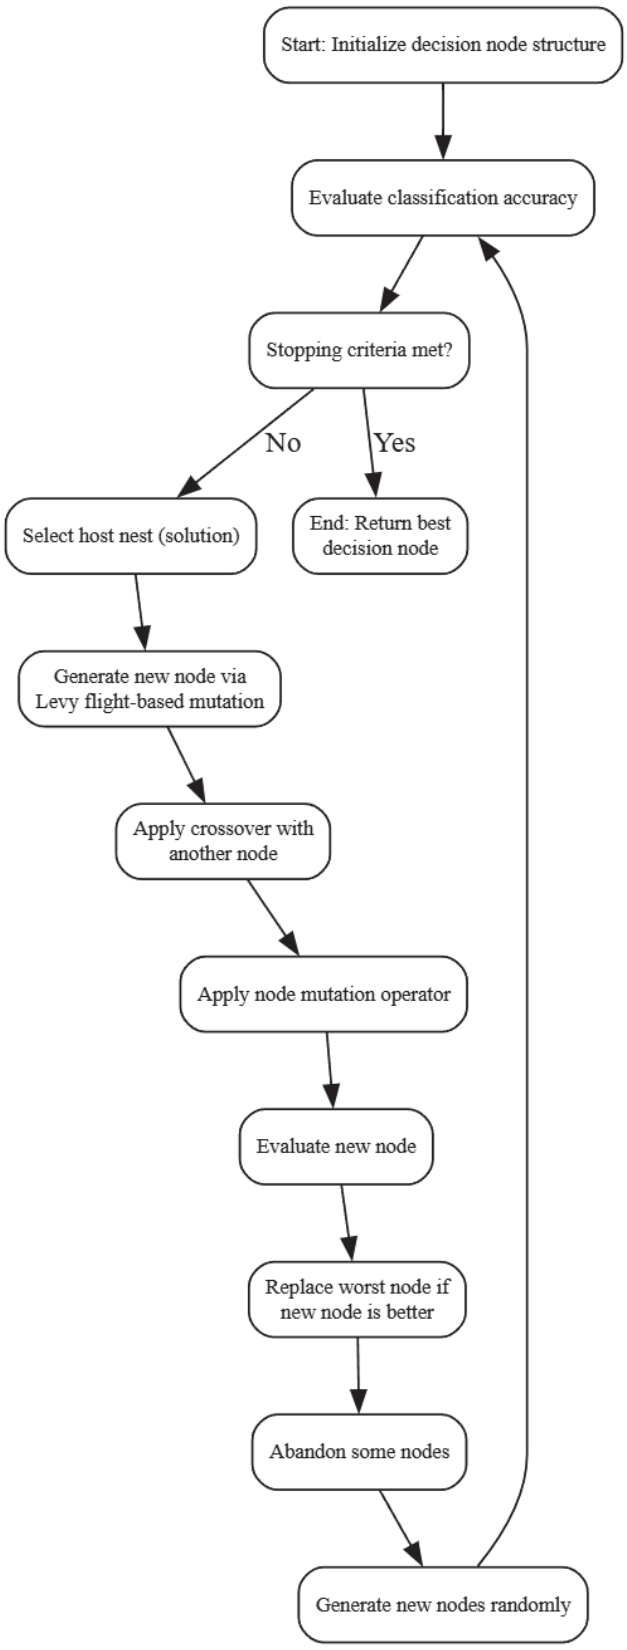

Fig 1. Process of finding solution elements in the tree

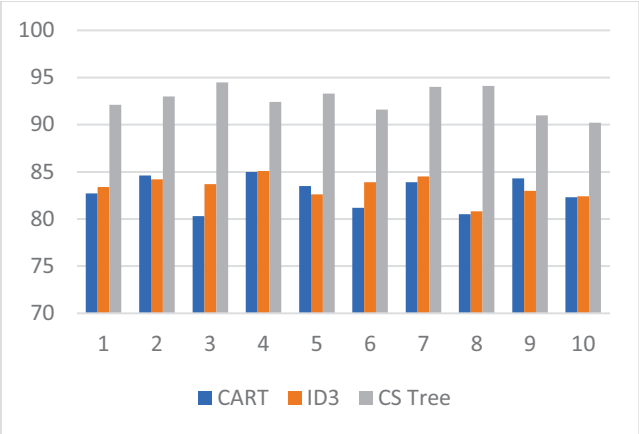

Fig 2. Comparison of CART, ID3, and Cuckoo Search Tree (CS Tree) algorithms by accuracy

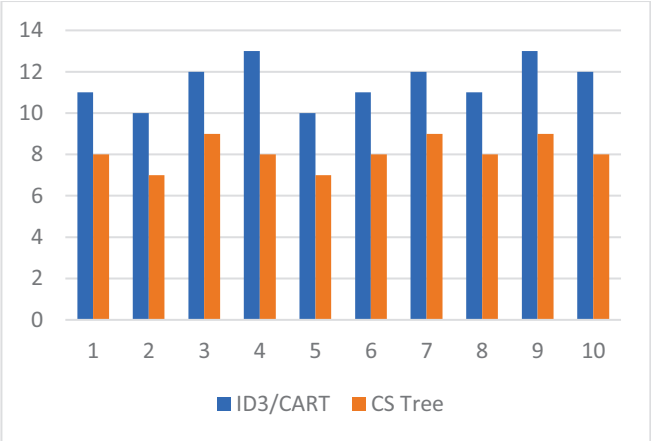

Fig 3. Comparison of CART, ID3, and Cuckoo Search Tree (CS Tree) algorithms by tree depth

Fig. 3 demonstrates the distribution of tree depths with and without evolutionary approaches. For the CART and ID3 algorithms, the tree depths were the same within each task. The trees obtained through evolutionary methods do not exhibit excessive depth, indicating an absence of overfitting and better generalization ability of the model. However, it should be noted that the resulting decision tree has a larger number of nodes; unlike classical algorithms, the tree is more balanced in structure.

The obtained results confirm the feasibility of using evolutionary approaches for constructing a single tree as a base element of more complex systems, particularly in the context of subsequent ensemble formation.

V. Conclusions

This work proposes a new approach to decision tree construction for the task of identifying the state of a computer system using the cuckoo search evolutionary algorithm. The main focus is on optimizing the parameters of the nodes within a single tree. A method for modifying thresholds and features in the tree nodes through mutation and crossover is proposed, allowing avoidance of local minima during tree construction and achieving better overall model quality.

Experimental research based on the department's dataset showed an improvement in classification accuracy after applying evolutionary optimization. An average increase in classification accuracy of 7–10% was achieved compared to standard tree construction. At the same time, a reduction in the average tree depth was also observed, which positively impacts the model's interpretability and computational efficiency.

Thus, the application of the cuckoo algorithm as a metaheuristic for constructing a single optimized decision tree demonstrates high effectiveness in classification tasks. Unlike approaches focused on ensembles, this method allows creating an efficient base classifier that can potentially be used either as a standalone model or as a component of an ensemble.

Future work may include expanding the approach by combining it with other types of evolutionary algorithms and investigating the impact of different fitness functions on the quality of the constructed model.

***Abstract* – The paper considers automated methods of cardiac diagnostics with a preliminary conclusion about cardiac arrhythmias in a patient. The importance of this task stems from insufficient sensitivity to rare pathologies, difficulties in interpreting combined diagnoses and dependence on medical validation significantly limit the capabilities of modern methods for diagnosing cardiovascular diseases. The comparative analysis of methods for computer diagnostics of cardiac arrhythmias conducted in this study showed that one of the most effective methods is the use of binary classifiers based on the logistic regression model. The most informative features were identified by analyzing the multiple regression coefficients and assessing their statistical significance. The following parameters of heart rate variability were used as independent features to form the input data for the model: SDNNi, NN50, pNN50, CV, Mo, VR selected depending on their statistical significance and confidence levels. The paper builds a logistic regression model, which was tested on a test sample. The experiment showed that the obtained logistic regression model achieves satisfactory classification performance, with a specificity of at least 87% and a sensitivity of 77%.**

Keywords – electrocardiogram, cardiac arrhythmia, heart rate variability, logistic regression, RR intervals, Newton-Raphson method, vegetative balance index.

I. Introduction

The issue of timely diagnosis and treatment of cardiovascular diseases is critical not only in Ukraine but also in other countries, as it is becoming one of the leading causes of death from heart failure. A timely diagnosis significantly increases a patient's chances of successful recovery. Therefore, exploring new methods and approaches for early diagnosis of cardiac arrhythmias based on the latest advancements in digital technology is highly relevant in modern medicine. However, expert analysis requires highly qualified medical specialists and may be subject to errors. due to the subjectivity of assessments, sometimes providing inadequate evaluations.

Modern cardial diagnostics has access to a wide range of methods, among which the most common and accessible is electrocardiography. In electrocardiography, various digital signal processing techniques are used to detect and analyze the main components of the electrocardiogram (ECG), typically involving three stages: signal processing, feature extraction, and parameter analysis. The literature presents a number of methods for automated diagnosis of cardiovascular diseases, both with pre-trained classifiers and adaptive ones [1, 2].
